### WISCONSIN SAW LOG PRODUCTION BY COUNTY AND SPECIES, 1973

James E. Blyth, *Principal Market Analyst*,  
Eugene F. Landt and James W. Whipple, *Forest Products Marketing &  
Utilization Specialists, Wisconsin Department of Natural Resources*  
and

Jerold T. Hahn, *Mensurationist*

**ABSTRACT.**--Shows 1973 saw log production by county of origin for 24 species groups. Discusses production changes since 1967, the last year of detailed data, in major species and reasons for the change:

**OXFORD:** 526(775):792. **KEY WORDS:** red oak, aspen, elm, hard maple, white pine, lumber.

In 1973 Wisconsin loggers harvested 386.5 million board feet of saw logs, 42 percent more than in 1967, the last year of detailed data. The large log harvest was in response to the heavy demand for railroad ties and lumber for furniture, flooring, pallets, crating, and construction. Lumber inventories were low during 1973 because sawmills had difficulty meeting the demand.

Principal species cut were red oak (84.7 million board feet), aspen (74.3 million board feet), elm (58.1 million board feet), hard maple (39.1 million board feet) and white pine (23.6 million board feet) (table 1).

Wisconsin mills received nearly all the saw logs cut in 1973; only 3.8 million board feet of logs were shipped out of State, primarily to mills in Michigan, Iowa, and Minnesota.

Major production gains since 1967 were in aspen (43.6 million board feet), elm (27.2 million board feet), and red oak (11.6 million board feet). Aspen has found widespread acceptance as pallet lumber and for furniture parts since 1967.

In addition, more aspen is used in housing construction since it became eligible for construction lumber grading under softwood rules. Elm harvesting increased because Dutch Elm Disease spread in Wisconsin and many dead and dying trees were salvaged for saw logs. Red oak harvesting increased to meet greater demands for furniture stock and railway ties.

Northeast Wisconsin furnished 38 percent of the saw log volume. Ten of the 15 large Wisconsin sawmills (those cutting 5 million board feet or more of lumber annually) are in the Northeast Unit and received large volumes of logs from that area. Half of the aspen was cut in the Northeast, 48 percent of the elm, and 55 percent of the hard maple. Pulpwood and veneer logs are in heavy demand in this Unit, also.

Top-producing counties were Shawano (including Menominee County), Forest, Marathon, and Oneida. Saw logs were harvested in every county except Kenosha.

These results came from a study of Wisconsin industrial roundwood production in 1973. The study was a cooperative effort between the Wisconsin Department of Natural Resources (DNR) and the North Central Forest Experiment Station. Sawmills using Wisconsin logs and bolts reported their roundwood receipts by species and county of origin in Wisconsin. Their cooperation is gratefully acknowledged. Special thanks are given to Area Foresters and Assistant Area Foresters of the Wisconsin DNR for personally canvassing the Wisconsin mills.

Table 1.--Saw log production by  
(In thousand board)

RELEASE ACCELERATES GROWTH OF YELLOW-POPLAR

AN 18-YEAR LOOK

Robert D. Williams, *Principal Silviculturist*  
Bedford, Indiana

**ABSTRACT.**--Yellow-poplar seedlings that germinated and were completely released from woody competition in 1957 (the first year after a harvest cut) were four times taller and five times larger in diameter after the 1973 growing season than seedlings that were not released.

**OXFORD:** 236.1:231:231.331:176.1 *Liriodendron tulipifera*. **KEY WORDS:** *Liriodendron tulipifera* L., germination date, seedbed scarification, natural regeneration, harvest cutting method.

Yellow-poplar (*Liriodendron tulipifera* L.) reproduction is usually abundant immediately after harvest cuts if seed is adequate. However, yellow-poplar will not grow well in the new stand unless the environment is favorable.

Results from a study in southern Indiana show that young yellow-poplar trees will survive under a high overstory but grow much faster if released. So if yellow-poplar is wanted in the new forest, stands containing yellow-poplar should be clearcut when harvested. Residual trees larger than 5 feet tall should be cut or killed.

### METHODS

The study was conducted in a mixed hardwood stand on the Hoosier National Forest near Oriole, Indiana. The area is a

broad ridge on Zanesville soil that has a site index of 60 for black oak and 70 for yellow-poplar. A harvest cut in the fall of 1956 reduced basal area from about 100 to 40 square feet per acre. The area had been heavily seeded by nearby yellow-poplar seed trees, and in the spring of 1957, about 10,000 yellow-poplar seedlings per acre were counted in the study area.

In July 1957, twelve 0.1 acre plots were established to find out how overhead release would affect survival and development of the new seedlings. Three intensities of release were tried:

1. Complete release--all woody vegetation over 5 feet tall was cut or frill girdled and poisoned, leaving a basal area of 0.
2. High release--all residual trees larger than 6 inches d.b.h. were cut or girdled and poisoned. Residual basal area of trees less than 6 inches was about 17 square feet per acre.
3. Check--no release, other than the timber harvest made in the fall of 1956, which left about 40 square feet of basal area per acre, mostly in cull and nonmerchable trees. Normally, cull trees are girdled and poisoned following harvest cuts.

The three treatments were replicated four times. Reproduction was sampled in six

permanent, randomly located, circular, mil-acre "quadrats" in each plot. Each of the 72 "quadrats" was established at least 20 feet from the plot boundaries.

When the initial germination counts were made in July 1957, three seedbed conditions were recognized: (1) undisturbed litter, (2) scarified organic matter (usually strips along skid trails and around stumps), and (3) mineral soil (usually skid trails and loading areas). Each "quadrat" was diagrammed to show seedbed condition classes and slash accumulation.

Yellow-poplar stocking on the 72 "quadrats" averaged more than 10,000 seedlings per acre in July. Seedling distribution varied, however, according to ground scarification and slash accumulation, from 0 to 61 seedlings per "quadrat." When the "quadrats" were remeasured in September 1957, 88 percent of them contained at least one yellow-poplar seedling and 74 percent were stocked with more than one. The largest number of yellow-poplar seedlings germinated the first year after the harvest cut. But a substantial number germinated the second year and several germinated as late as the fifth year after the cut (table 1). In the spring of 1959, 78 percent of the "quadrats" were stocked with at least one seedling that germinated in 1958. And in the spring of 1962, 49 percent of the "quadrats" were stocked with one or more seedlings that germinated between 1959 and 1961.

Table 1.--Yellow-poplar seedlings per acre by release treatment and the year germinated

(In numbers)

| Year seed germinated | Years after harvest cut | Release treatment |        |          |
|----------------------|-------------------------|-------------------|--------|----------|
|                      |                         | Check             | High   | Complete |
| 1957                 | 1                       | 7,583             | 13,500 | 10,750   |
| 1958                 | 2                       | 7,875             | 6,668  | 3,208    |
| 1959-1961            | 3-5                     | 3,125             | 1,792  | 1,582    |

## RESULTS

*Survival.*--Eighteen-year results show that yellow-poplar seedlings that germinate immediately after logging have a much better chance of becoming established in the new stand than seedlings that germinate later, even if only 1 year later (table 2). Although survival of the 1957 seedling crop seems low, there are still about 1,100, 1,800, and 1,100 trees per acre remaining

Table 2.--Survival of yellow-poplar seedlings at 18 years by release treatment and year the seed germinated

(In percent)

| Year seed germinated | Release treatment |      |          |
|----------------------|-------------------|------|----------|
|                      | Check             | High | Complete |
| 1957                 | 14                | 13   | 10       |
| 1958                 | 7                 | 4    | 4        |
| 1959-1961            | 7                 | 0    | 3        |

in the check, high release, and complete release plots, respectively.

Late germinators survived best in the unreleased plots. During the winter of 1958-1959 more than 20 percent of the mortality on the released plots was caused by mice, while no mouse damage was found on the unreleased plots. Apparently, the heavier ground cover of grass, herbs, and slash on the released plots provided a better habitat for mice than the more sparse ground cover on the unreleased plots.

Scarification greatly affected initial germination. When the study was established in 1957, three-quarters of the seedlings were found on the disturbed forest floor<sup>1/</sup> (scarified organic matter and mineral soil) which made up only a little more than one-quarter of the area (table 3). However, degree of scarification had no effect on long-term survival; 18 years after the harvest cut survival of the 1957 seedling crop was 14 percent in the undisturbed litter, 13 percent in the scarified organic, and 14 percent in the mineral soil.

Table 3.--Initial surface condition classes and distribution of yellow-poplar seedlings

| Seedbed     | Area | Number       | Seedlings |
|-------------|------|--------------|-----------|
|             |      | of seedlings | per acre  |
|             |      | Percent      | Number    |
| Undisturbed | 73   | 23           | 3,200     |
| Scarified   | 17   | 50           | 30,900    |
| Mineral     | 10   | 27           | 27,200    |
| Total       | 100  | 100          |           |

<sup>1/</sup> Engle, LaMont G. and Robert D. Williams. 1957. Scarifying seedbed boosts yellow-poplar germination. USDA For. Serv., Cent. States For. Exp. Stn. Stn. Note 110, 2 p.

"Quadrats" stocked with one or more seedlings, regardless of year germinated, decreased from 92 percent to 62 percent from the 5th to the 18th year. Nevertheless, yellow-poplar remains a major component of the new stand. Thirty-one percent of the trees on the check plots and 40 percent of those on both the high and complete release plots are yellow-poplar. And if present, yellow-poplar is the tallest species on 67 percent of the check plot "quadrats," 81 percent of the high release "quadrats," and 75 percent of the complete release "quadrats."

*Growth.*--Eighteen years after the harvest cut, the tallest 1957 trees in the complete release plots are more than four times taller than the 1957 trees in the check plots (table 4). Also, the tallest yellow-poplar trees of those that germinated the first year after the harvest cut are more than twice as tall as the tallest of those that germinated only 1 year later, regardless of release treatment.

Eighteen years after the cut, 38 of the 72 "quadrats" contained at least 1 yellow-poplar from the 1957 crop. Only 1 of these 38 "quadrats" contained a later germinator that was taller than the 1957 tree.

Degree of scarification had little effect on height growth. Height of the

Table 4.--Mean height of tallest yellow-poplar per "quadrat" by release treatment and age of the tree 18 years after the harvest cut

| Year seed germinated | Tree age | Release treatment |      |          |
|----------------------|----------|-------------------|------|----------|
|                      |          | Check             | High | Complete |
| - - - - Feet - - - - |          |                   |      |          |

| 1958                 | 16       | 2.7               | 4.6  | 10.4     |
| 1959-1961            | 13-15    | 1.4               | --   | 0.4      |
| 1962-1973            | 1-12     | 3.5               | --   | --       |

tallest yellow-poplar in each ground condition class averaged 19 feet for the undisturbed litter, 18 feet for the scarified organic, and 16 feet for the mineral soil.

Diameter growth was increased by release, too. Mean diameter of the largest trees in the complete release plots is about five times greater than that of the largest trees in the check plots (fig. 1). Mean d.b.h. of the largest yellow-poplar per quadrat is 0.5 inch in the check plots, 1.1 inch in the high release, and 2.7 inches in the complete release.

#### CONCLUSIONS

Eighteen years after a timber harvest, several facts concerning the reproduction, survival, and growth of yellow-poplar are evident:

Figure 1.--Completely released yellow-poplar (left) are typically much larger than unreleased trees (right) that survive under an overstory

1. Yellow-poplar germinates best on a scarified seedbed, but neither survival nor growth are dependent on the degree of scarification.

2. Yellow-poplar will survive under a partial overstory (40 sq. ft. of basal area), but growth is very slow. Trees completely released are four times taller and five times larger in diameter than unreleased trees.

3. Although there is no difference in survival between high release trees and completely released trees, the difference in growth is notable. Completely released trees are almost twice as tall and their diameter is more than twice that of the high release trees.

4. Yellow-poplar competes well with other species, especially in openings. Yellow-poplar has a better than average

chance of being taller than its neighbor under a partial overstory, but if released, yellow-poplar may be taller than its neighbor 75 percent of the time.

5. Yellow-poplar that germinated the first growing season after a cut has a much better chance of becoming established in the new stand.

6. Yellow-poplar seedlings can be released, but the cheapest way to favor yellow-poplar in the new stand, when seed trees are nearby, is to completely clear the regeneration area when the old stand is harvested. Because viable yellow-poplar seed accumulates in the litter, the seed trees may be cut when the rest of the stand is harvested.<sup>2/</sup>

 LIBRARY

**ABSTRACT.**--Weeds must be controlled for at least 3 years to successfully establish walnut plantations. Whether by cultivating or applying chemicals, a strip or spot 4 feet wide is sufficient the first 2 years, followed by a 6-foot spot or strip for the third and fourth years.

**OXFORD:** 236.1:176.1 (*Juglans nigra*). **KEY WORDS:** herbicides, cultivation, *Juglans nigra*, ground preparation, chemical.

Weed control in walnut plantations is now considered standard operating procedure. Landowners and plantation managers who ignore or try to shortcut this important step soon discover that in a race with the weeds for moisture, nutrients, and light, walnut trees seldom win. The type and amount of weed control depends on whether the site is a field or cut-over forest, the other cultural operations planned, and the owners' objectives.

### MECHANICAL VERSUS CHEMICAL CONTROL

Cultivation and/or chemicals can be used successfully to control weeds in walnut plantations. Mechanical control is more costly, but if the landowner has a tractor and cultivator, this may be the best alternative. To keep weeds from getting taller than 6 inches, three to six cultivations per year are necessary. A disc or rototiller

can be used, but be careful not to damage the stems and shallow feeder roots.

Mowing does little to reduce the competition for moisture and nutrients and so is not a substitute for cultivation or chemical weed control. When weeds are controlled in strips or around individual trees, tall grass and weeds between the rows can protect walnut trees from wind (Schneider *et al.* 1968). On the other hand, however, mowing may be helpful by making it easier to walk through the plantation for other cultural operations and by reducing the fire hazard by keeping the vegetation on the ground.

Mulching with plastic, sawdust, bark and wood chips can control weeds, but these materials have some disadvantages. Plastic is expensive, takes a lot of time to install, may cause heat girdling damage, and provides cover for mice that girdle small trees. Wood chips, sawdust, and bark also take a long time to apply and may tie up soil nitrogen adversely affecting the trees. Trees usually grow slower when mulched than when cultivated or chemically treated (Bey *et al.* 1976, Erdmann 1967, von Althen 1971).

Herbicides have been used successfully for weed control in walnut plantations. However, herbicides can be used only if it so specifies on the container label and is

not limited by a State or Federal regulation.<sup>1</sup> Don't assume from general statements on the label that the herbicide may be used indiscriminantly. For example, some chemicals designated as weed killers and/or soil sterilants may kill your walnut trees, too. If you have any doubt about proper use, check with an herbicide authority before proceeding.

Simazine is registered for weed control in walnut plantations that have been established 1 year or more. It is a pre-emergent chemical that acts primarily on germinating seeds. Rates of 4 pounds per acre are recommended for sandy-loam soils and 5 pounds per acre for the heavier clay-loam soils. Simazine is partially effective in killing established grasses but not woody perennials such as trumpet vine. Grasses are easily killed by dalapon at a rate of 5 to 10 pounds per acre. At present, dalapon is not registered for use in walnut plantations, but Dow Chemical Company<sup>2</sup> is considering a label change to include dalapon for use in walnut plantations. Phenoxy chemicals such as 2,4-D will kill a variety of annual and biennial broadleaf weeds. However, if sprayed on the leaves or injected into the trunk, they will also kill trees. Although these chemicals are registered for use on weeds in golf courses, parks, and cemeteries, the container labels for these chemicals do not say "walnut plantations" *per se*.

### SOD VERSUS PREPLANT TILLING

Although plowing and discing before planting are not necessary for successful

<sup>1</sup>This publication reports research involving pesticides. It does not contain recommendations for their use, nor does it imply that the uses discussed here have been registered. All uses of pesticides must be registered by appropriate State and/or Federal agencies before they can be recommended.

CAUTION: Pesticides can be injurious to humans, domestic animals, desirable plants, and fish or other wildlife--if they are not handled or applied properly. Use all pesticides selectively and carefully. Follow recommended practices for the disposal of surplus pesticides and pesticide containers.

<sup>2</sup>Mention of trade names does not constitute endorsement of the products by the USDA Forest Service.

plantation establishment, trees planted in plots prepared by plowing or discing will eventually outgrow those planted in sod. (fig. 1). In our studies the differences between sod and plowed plots did not show up until the third or later years. Jaciw (1974) also reports better performance of young walnut trees planted on cultivated rather than sod plots.

Figure 1.--After 5 years, height growth of walnut trees was greater in plots that were tilled before planting than in plots where trees were planted in sod.

One effect of plowing grassy fields before planting is the conversion of the ground vegetation to predominantly broadleaf weeds. Simazine works effectively on germinating weed seeds, so weed control with simazine is more complete on areas prepared by plowing than on established sod (Erdmann 1967). On the other hand, plowing may encourage the development of trumpet vine, a weed that can be troublesome in plantations for 10 years.

### COMPLETE VERSUS PARTIAL CONTROL

It is not necessary to control weeds over the entire area for maximum growth of walnut trees. Treating spots or strips is cheaper than complete control and reduces the chances of erosion. Even on very gentle slopes, erosion can become severe where there is complete weed control over the entire plantation.

The spot diameter or strip width need not be wider than 4 feet for the first 2 years and 6 feet for the third and fourth years. In studies in southern Illinois and Indiana, there were few differences among spot sizes after 2 years. During the third and later years there appears to be some

advantage to increasing the size of the weed control spot beyond 4 feet in diameter (fig. 2). The trees in the 4-, 6-, and 8-foot diameter treatments grew larger than those in the control and 2-foot spots. This and other studies suggest that as we continue weed control beyond the first few years the width of the weed control strip should be increased for maximum growth.

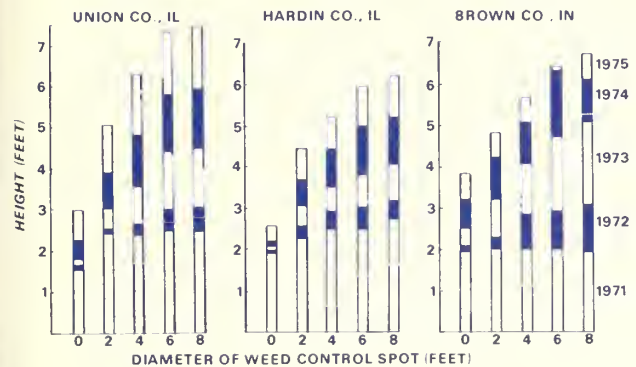

Figure 2.--During the third and later years, height growth of walnut trees can be increased by controlling weeds in spots greater than 4 feet in diameter.

In another experiment in southern Illinois, we controlled weeds for the first 7 years with chemicals (simazine + dalapon + 2,4-D amine) in strips 4 to 20 feet wide, plus a control. No weed control was done during the eighth year. For the first 4 years, there was no gain in height made by spraying in strips wider than 4 feet. Then during the last 4 years, the trees in the wider strips grew taller and larger in diameter than those in the narrow strips (fig. 3).

Whether or not to spray spots larger or strips wider than 4 feet is uncertain at this time. For spraying spots in a plantation with a 12- by 12-foot spacing, and using simazine at 5 pounds per acre, costing \$3.50/lb, the cost of the chemical per acre would be as follows:

| Spot diameter (feet) | Cost of simazine/acre |
|----------------------|-----------------------|
| 4                    | \$ 1.53               |
| 6                    | 3.43                  |
| 8                    | 6.10                  |
| 10                   | 9.54                  |
| 12                   | 13.73                 |

Figure 3.--In an experiment in southern Illinois, trees with weed control in strips wider than 4 feet grew larger than those in narrower strips.

We feel that if spraying is continued for more than 2 years, spot size should be increased to 6 to 8 feet in diameter. The additional cost of materials would be minor compared to the expected return. To go from 4- to 8-foot spots would mean an additional cost of less than \$5/acre for chemicals plus a small amount for additional labor. The additional chemical cost compounded for 40 years at 10 percent will amount to about \$225, but probably less than the increased value due to the additional weed control.

### 1, 2, 3 OR MORE YEARS OF CONTROL

Weeds should be controlled for at least 3 years in black walnut plantations for maximum growth. In experiments in Indiana and Iowa, we compared three weed control treatments (simazine, atrazine, and cultivation) for 1, 2, and 3 years. In both States, tree growth was greater when weeds were controlled for 3 years than for 2, and for 2 years than for 1 (fig. 4). The differences in growth due to treatment varied by State and may be partially explained by the intensity of the cultivation received. In Iowa no weeds were allowed to grow in the cultivated plots,

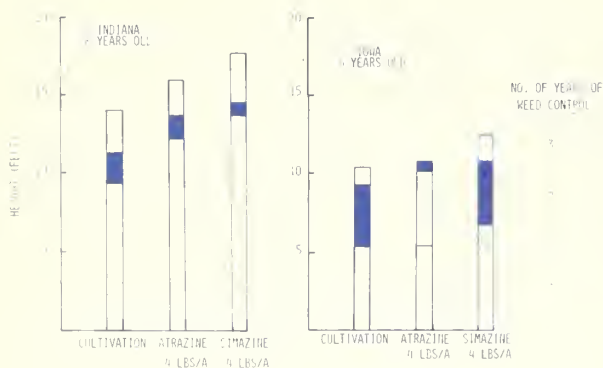

Figure 4.--In two plantations, walnut growth was generally greater when weeds were controlled for 3 years than for 2, and for 2 years than for 1.

while in Indiana the plots were not cultivated until the weeds were quite dense.

By controlling weeds in wide strips or spots during the fourth and later years, we believe that we will get faster tree growth. Yet, the answer to the question of whether or not it is worth the extra cost is not clear. Costs for chemical weed control probably will not exceed \$25/acre at current prices. To get a 10 percent return on the \$25 over the next 40 years, we need to receive an increase of \$1,131/acre due to the additional weed control. It is questionable if weed control beyond 3 years is an economically sound practice. From the biological standpoint, it seems reasonable that we should continue weed control until the crown is large enough to shade out some of the competing weeds. On good sites and at a 10- by 10-foot spacing, crowns will begin overlapping at about age 5. Weed control should be continued for at least 3 years, but not longer than when crowns begin to close and shade out competing weeds.

#### DISCUSSION

People plant walnut trees for many different reasons, and the weed control practice that is best for one grower may not be suitable for another. For some, mowing may increase the value simply by making it easier to walk through the plantation, while for others this may not be important. Other interacting factors that

influence decisions regarding weed control include spacing, interplanting, kinds of weeds present, and site quality. In addition, all weed control is not alike. Two years of excellent control may benefit survival and growth more than 3 years of moderate control. Although weed control practices described in this paper refer to planting on old fields, the principles are the same for cut-over forest land (Krajicek 1975). Control of herbs, grasses, and brush for several years provides for maximum growth of walnut trees.

One of the most important things you can do to increase growth of walnut trees during the first few years is to control weeds. Without weed control, plantations are likely to fail. Yet weed control is neither a cure-all nor a substitute for other management operations. By combining weed control with proper seed source selection, site selection, pruning, thinning, and pest management, maximum production in walnut plantations will be obtained.

## SOIL CONDITIONS AFFECT GROWTH OF HARDWOODS IN SHELTERBELTS<sup>1/</sup>

Willard H. Carmean, *Principal Soil Scientist*

**ABSTRACT.**--Large growth differences were found for hardwoods in shelterbelts on three contrasting soils of western Minnesota. Five years after planting, height growth was outstanding for green ash and Russian olive planted on a moderately fine-textured, somewhat poorly drained soil. Growth was much poorer on coarse-textured or shallow soils. Size of planting stock was not related to growth of trees after planting. OXFORD: 266: 181.32:176.1(776). KEY WORDS: tree growth, stock size.

### THE STUDY AREA

Shelterbelt plantings were made in 1968 on the following three contrasting soils in Swift County, Minnesota:

(1) *Renshaw sandy loam* (Udic Haploboroll, fine-loamy over sandy or sandy-skeletal, mixed). This excessively drained soil has a shallow sandy loam surface soil overlying calcareous outwashed glacial sand and gravel. Topography is level and this soil is considered very droughty.

(2) *Buse loam* (Udorthetic Haploboroll, fine-loamy, mixed). This well drained soil has a very dark-colored loam surface soil overlying calcareous loam and clay loam glacial till. Mottling is evident in the subsoil at about 40 inches indicating moderate permeability. Topography is a knob on a rolling landscape, and surface soils are shallow on the steeper slopes because of past erosion.

(3) *Colvin silty clay loam* (Typic Calciaquoll, fine-silty, frigid). This somewhat poorly drained calcareous soil has developed from glacial lacustrine deposits. Topography is level, internal drainage is slow, and the subsoil is mottled and very calcareous at shallow depths.

Shelterbelts are used in the central plains for protecting fields and homesteads (Read 1964, Stoeckeler 1970). But tree growth in shelterbelt areas, as well as in forested regions, differs greatly depending upon the soil and climate where trees are planted. Thus, selecting tree species for shelterbelt plantings requires information about their adaptability to local soil and climatic conditions. Our studies in western Minnesota reveal large differences in growth for trees planted on soils widely different in texture, depth, and internal drainage.

Annual rainfall averages about 22 inches per year. The Renshaw area is 15 miles west of the other two areas, and thus may have lower rainfall and greater evapotranspiration.

<sup>1/</sup> A cooperative study with the Minnesota Division of Lands and Forestry. We thank State personnel who provided the seedlings and the planting areas and who assisted with planting, cultivation, and tree measurements.

## METHODS

Three species commonly used in shelter-belts were planted in each of the three areas: (1) 3-0 green ash (*Fraxinus pennsylvanica* Marsh); (2) 2-0 Russian olive (*Elaeagnus angustifolia* L.); and (3) 3-0 Siberian peashrub (*Caragana arborescens* Lam.).

Trees were planted 2 feet apart in rows 15 feet apart. On each area, 24 plots were used for each of the three species--a plot was a portion of a row containing 9 to 18 trees. Three stock sizes were used for each species, and each stock size was replicated in eight plots in a completely randomized statistical design (table 1).

Table 1.--Tree species and the size of seedlings planted in each of the three soil areas (In inches)

| Stock size | Tree species            |                            |                     |                            |                 |                            |

| Small      | 9.5                     | 0.10-0.17                  | 9.8                 | 0.10-0.23                  | 9.5             | 0.10-0.17                  |

<sup>1/</sup> Stem diameter measured 1 inch above the root collar.

Each planting area was plowed and disked in the fall of 1967, and planting was done in May 1968 using a machine planter. All trees were checked to ensure proper planting. Weeds were controlled by cultivation and hand weeding during the first three growing seasons, but only occasional cultivation was done in the fourth and fifth growing seasons.

## RESULTS

### Survival

Survival of Siberian peashrub and green ash was excellent on all soils regardless of stock size (table 2). Large Russian olive also had excellent survival on all soils, but survival was usually poorer for medium- and small-sized Russian olive. This generally excellent survival probably was due to: (1) favorable weather conditions (cloudy and rainy) during planting; (2) checking to ensure proper planting; and (3) controlling weeds.

Most of the mortality resulted from accidental uprooting or burying of the smaller seedlings when they were cultivated during the first and second growing seasons. For Russian olive, uprooting or burying was particularly severe for small- and medium-sized seedlings and, in the Renshaw area, survival of Russian olive also was reduced by flooding in 1969.

### Size of Planting Stock

Size of planting stock was significantly related to annual height growth in only a few cases, and few consistent trends were evident. For the three species on each soil area, most large-, medium-, and small-sized seedlings grew similarly in

Table 2.--Five-year survival on the three soil areas by tree species and seedling stock size (In percent<sup>1/</sup>)

| Soil series and stock size <sup>2/</sup> | Tree species      |               |           |

| small                                    | 72                | 24            | 88        |
| Colvin large                             | 94                | 96            | 98        |
| medium                                   | 92                | 90            | 98        |
| small                                    | 88                | 68            | 92        |

<sup>1/</sup> For each species the survival percents not connected by the same line are significantly different (5-percent level) as determined by the Newman-Keuls (Hartley modification) multiple range test.

<sup>2/</sup> See table 1 for stock height and caliper.

<sup>3/</sup> Survival of medium- and small-sized seedlings was reduced by flooding in 1969.

height for each of the 5 years following planting; most seedlings that were tall at the time of planting were taller by about the same amount after five growing seasons.

### Soil Area

For each of the three species on each soil area, we averaged annual height growth for all 24 plots because few significant growth differences were evident due to seedling stock size. Then we compared both total and annual height growth and found that growth of two species differed greatly on the three soils (fig. 1). Siberian peashrub is a slow-growing shrub, and we found similar growth on the three soils. But growth for both Russian olive and green ash was outstanding on the moderately fine-textured Colvin soil. After 5 years, total height of Russian olive and green ash planted on the Colvin soil averaged 12.3 and 9.6 feet, respectively. In contrast, Russian olive and green ash grew very slowly on the coarse-textured Renshaw soil, and after 5 years total height averaged only 3.3 and 2.7 feet, respectively. Green ash was 22 percent taller on the medium-textured, shallow Buse soil than on the coarse-textured Renshaw soil. Russian olive, however, was only slightly taller on the Buse than on the Renshaw soil after 5 years.

### CONCLUSIONS

For the first 5 years after planting, we found similar growth for large-, medium-, and small-sized seedlings. Hence, we conclude that seedling stock size was not closely related to growth of trees planted in our three shelterbelt areas. These results contrast with other studies that show stock size is related to growth of shelterbelt trees (George and Frank 1973). There are two possible reasons for this difference. First, our seedlings were carefully cultivated for the first 3 years after planting, thus early competition from grasses and weeds was controlled. Possibly, stock size would be more closely related to growth and survival where grass and weeds overtop and compete with small-sized seedlings. Second, none of our seedlings had a stem caliper less than 0.10 inch; close to the minimum caliper recommended for hardwoods (Limstrom 1963, Stoeckeler 1937, Stoeckeler and Jones 1957, Williams and Hanks In press). Poorer growth might have been observed if we had also included a very small seedling size class.

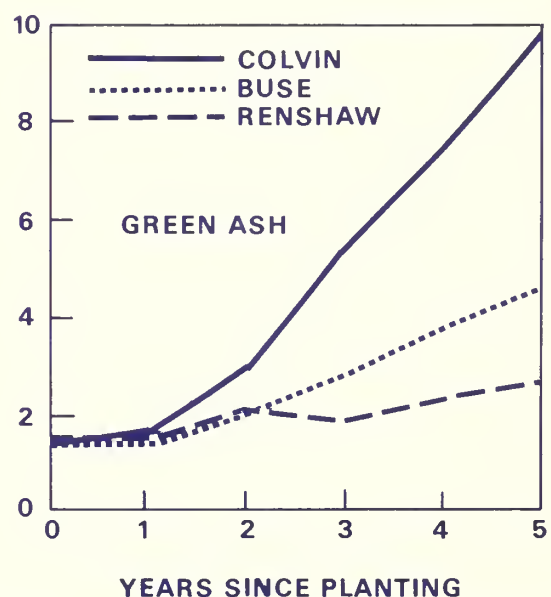

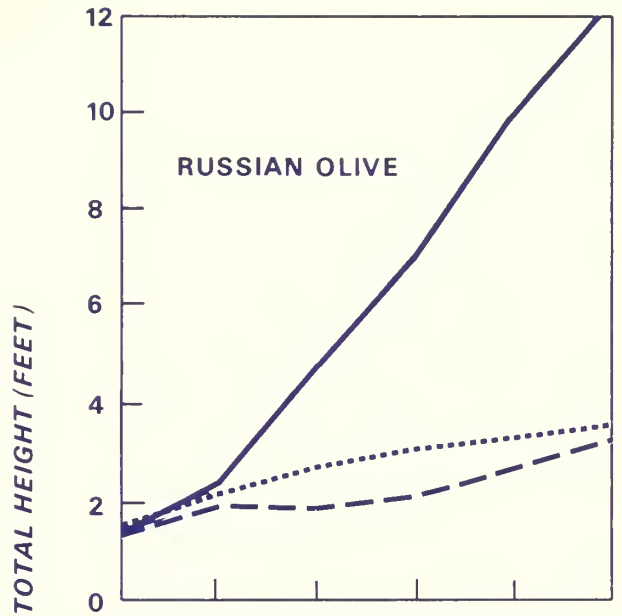

Figure 1.--Average height growth for Siberian peashrub, Russian olive, and green ash planted on three contrasting soils of western Minnesota.

Even though we did not observe any growth differences related to stock size, we conclude that large-sized seedlings are still preferable for shelterbelt planting. Large seedlings are easier to see, and thus are less likely to be uprooted or buried during cultivation. Also the greater initial height of large seedlings help them outgrow grass and weed competition sooner so less cultivation would be required for seedlings that are large at the time of planting.

The major finding of our study is that growth differs greatly on soils contrasting greatly in texture and drainage. Outstanding growth occurred on Colvin--an imperfectly drained silty clay loam soil. Poor growth occurred on Renshaw--a droughty, excessively drained sandy loam soil. Tree growth was only a little better on the Buse loam than on the Renshaw sandy loam even though the Buse loam is somewhat finer in texture than the Renshaw soil. However, the Buse soil is located on a fairly steep knob, and soil is shallow because of past erosion.

We can conclude from this study that trees planted in shelterbelts, as well as agricultural crops, have markedly different growth depending upon the kind of soil where they are planted. Hardwoods planted in deep, imperfectly drained, fine-textured soils of western Minnesota, will grow well. Those planted in shallow, coarse-textured soils,

however, will grow slowly. Western Minnesota has a great variety of soils in addition to those of this study. Additional site studies are needed so that we can predict how well various shelterbelt tree species will grow when planted on different soils.

SNOWMELT RUNOFF FROM PLANTED CONIFERS  
IN SOUTHWESTERN WISCONSIN

Richard S. Sartz, formerly Principal Hydrologist, now retired

**ABSTRACT.**--Snowmelt overland flow was measured for one season from 10-year-old plantations of red pine, Norway spruce, European larch, and from old field control plots, on both north and south slopes. Pine and spruce plots produced more runoff than larch and old field plots; and south slope plots produced more runoff than north slope plots.

OXFORD: 116.2:116.21:174.7(775).

KEY WORDS: soil frost; infiltration.

Snowmelt runoff from frozen ground is the primary cause of spring floods in southwestern Wisconsin's unglaciated region. Natural deciduous forests rarely contribute, probably because of discontinuous or more permeable frost in the forest.<sup>1/</sup> However, because coniferous forests insulate the ground better than deciduous forests, they may retain frost in the spring longer than open land, and thus produce more runoff from melting snow than open land.<sup>2/ 3/</sup> If this is true, extensive planting of conifers could worsen floods in the region. This

note reports on a study conducted to determine if planted conifer stands produce more snowmelt runoff than natural deciduous forests.

## METHODS

The study was conducted on the Coulee Experimental Forest near La Crosse, Wisconsin on plantations established specifically for the purpose. Three species were studied: red pine (*Pinus resinosa* Ait.), Norway spruce (*Picea abies* L. Karst.), and European larch (*Larix decidua* Mill.). The trees were planted in 1964 and 1965 at a spacing of 2 by 2 m on 0.2 h plots. The three species were planted in four blocks, two each on opposite north- and south-facing slopes of 15 to 20 percent. Each block consisted of a 500-tree plot of each species and an unplanted control plot of the same size. The study area had been an alfalfa meadow or old field. The trees were hand-planted in scalps to avoid the influence of planting furrows on overland flow. The soil is an eroded loessal silt loam of the Fayette series (valley phase).

Overland flow from 4-by 8-m runoff subplots made of redwood borders and catchment troughs was monitored during snowmelt in 1975. The runoff water was piped to collecting tanks. One runoff subplot was centered in each planted and control plot (16 in all). Water caught in the troughs and tanks was kept from freezing by electric heat tapes. The tanks were measured and then emptied six times during the snowmelt period.

Snow and frost depth were measured at three points 5 m apart on each plot at the beginning of the runoff period. Measuring points on planted plots were midway between rows of trees. Frost depth was measured by modified Gondahl frost depth gages.<sup>4/</sup>

By 1975, the 10th year after planting, the pine and spruce were 3 to 4 m tall, and the larch were about 5 m tall. The larch canopy was closed, and the pine and spruce canopies were almost closed. The soil was almost completely covered with needles, mosses, and dead herbaceous growth on all plots, but the heaviest cover was formed by matted grass on the unplanted control plots.

### RESULTS AND DISCUSSION

At the beginning of the 1975 snowmelt period the average depth of the snowpack was 30 cm on south slope plots and 50 cm on north slope plots. Corresponding water equivalents were about 9 and 15 cm, based on snow density data from elsewhere on the experimental forest. The snowpack started melting about the middle of March. Most south slope plots were bare by April 7, but north slope plots still had a continuous snow cover--up to 40 cm deep in spots. The last snowmelt runoff was measured on April 16, at which time small patches of snow still remained on north-facing plots. Snow depth and rate of melt on individual plots varied with aspect, which ranged from 31° E to 43° W on south aspects, and from 52° E to 37° W on north aspects.

Pine and spruce plots produced much more runoff than larch and unplanted plots, and south slope plots produced more than north slope plots. Total snowmelt runoff from March 18 to April 16 was as follows:

|           | South-slope plot  | North-slope plot |
|-----------|-------------------|------------------|
|           | (In cm)           |                  |
| Pine      | 2.9 <sup>5/</sup> | 2.8              |
| Spruce    | 4.0               | 2.4              |
| Larch     | 1.2               | 0.1              |
| Unplanted | 1.3               | 0.3              |

Although the amount of runoff varied widely between replicates, runoff from the pine and spruce and the larch and unplanted were different (table 1). Expressed as a percent

1/ Estimated. Runoff tanks overflowed.

of the water content of the snowpack, runoff from south slope plots ranged from 14 to 42 percent, and from north slope plots, from 0.5 to 20 percent. Even with much more snow on the ground, north slope plots produced less runoff.

Most of the runoff from both slopes occurred during the period from March 18 to 24. However, the proportion measured on the first and last days of record was different on the two slopes (table 2).

| April 16  | 10           | 3       | 27          | 17     |

<sup>1/</sup> Means of two plots.

Frost incidence and depth as measured did not fully explain runoff differences. Frost was found at all three points only on one pine and one open plot; and none of the three sampling points was frozen on four of the eight spruce or pine plots. However, the measured frost values (taken at points midway between trees) probably did not reflect actual frost conditions under the canopies of the pines and spruces. Uneven distribution of snow caused by irregular shading and by interception and subsequent canopy dumping could have caused runoff differences between the pine and spruce plots, and the larch and open plots. Accumulation of ice on the soil surface from canopy drip could also explain the differences.<sup>2/</sup>

The results of this study support Harris' conclusion that planting pine and spruce can increase snowmelt runoff in the unglaciated area. They also show that where flood prevention is an important consideration in tree planting programs, larch should be favored over pine or spruce.

## THE EFFECT OF FOUR HERBICIDES ON THE SURVIVAL AND GROWTH OF NINE HARDWOOD SPECIES

Robert D. Williams, *Principal Silviculturist and*  
John E. Krajcek, *formerly Associate Silviculturist, now retired*  
Carbondale, Illinois

ABSTRACT.--To learn more about the tolerance of hardwoods to herbicides, the survival and growth of nine hardwood species were compared in plots either cultivated or treated with various herbicides applied at different rates, on prepared and unprepared ground, and before and after planting. Black walnut and white oak were very tolerant to all herbicides tested but American sycamore and European alder were highly susceptible to herbicide damage by all chemicals tested except dichlobenil.

plantations we must know if the same chemicals and rates can be used safely for all species in the mixture. A recent study shows great differences in first-year survival and growth among nine hardwood species treated with four weed control chemicals at different rates.

### METHODS

The study was established on the Shawnee National Forest in southern Illinois. The soil is Haymond silt loam, a well drained soil of the floodplain. It is slightly acid to neutral, moderately permeable, and has moderately high natural fertility.

OXFORD: 414.4:176.1. KEY WORDS: simazine, atrazine, amitrole, dichlobenil.

Stratified black walnut (*Juglans nigra* L.) seed and 1-year-old seedlings of nine

Many hardwood plantations fail in their early years because of heavy weed competition. Weeds can be controlled by cultivation, but the need for frequent cultivation and topographic limitations have restricted the use of mechanical control. The development of herbicides has made it feasible to control weeds in forest plantings at relatively low cost; chemical control is also less restricted by topography. However, herbicides may not be used in tree plantations unless such use is specified on the container label and is not limited by a State or federal regulation.<sup>1</sup>

<sup>1</sup>This publication reports research involving pesticides. It does not contain recommendations for their use, nor does it imply that the uses discussed here have been registered. All uses of pesticides must be registered by appropriate State and/or Federal agencies before they can be recommended.

CAUTION: Pesticides can be injurious to humans, domestic animals, desirable plants, and fish or other wildlife--if they are not handled or applied properly. Use all pesticides selectively and carefully. Follow recommended practices for the disposal of surplus pesticides and pesticide containers.

Information about the tolerance or susceptibility of various newly planted hardwood species to herbicides has been limited. To control weeds in mixed-species

hardwood species, including walnut, were used in the study. The other species were white ash (*Fraxinus americana* L.), white oak (*Quercus alba* L.), sweetgum (*Liquidambar styraciflua* L.), black locust (*Robinia pseudoacacia* L.), American sycamore (*Platanus occidentalis* L.), river birch (*Betula nigra* L.), yellow-poplar (*Liriodendron tulipifera* L.), and European alder (*Alnus glutinosa* L.).

Four weed-control chemicals were tried alone or in combination--(1) dichlobenil alone, (2) atrazine-simazine (1:1), and (3) amitrole-simazine (1:3)--and at three different rates (table 1). Dichlobenil was applied before planting only; the atrazine-simazine and amitrole-simazine mixtures were applied before and after planting. Site preparation and tree planting were done in April.

Table 1.--Weed control treatment

<sup>1</sup>Active ingredients (pounds per acre).

<sup>2</sup>Average of three plots. One contained 100 percent Johnsongrass 10 feet tall.

<sup>3</sup>b = before planting.

<sup>4</sup>p = plowed.

<sup>5</sup>a = after planting.

<sup>6</sup>n = not plowed.

The study area was an unimproved pasture that contained the native grasses plus scattered trumpet-creeper (*Campsis radicans* L.). Plots treated with dichlobenil and atrazine-simazine were prepared by plowing with a rotary tiller before the herbicides were applied. Plots treated with amitrole-simazine were not plowed before chemical treatment. The dichlobenil granules were broadcast, then lightly incorporated into the prepared soil. The wettable powder formulations of atrazine and simazine and the soluble powder formulation of amitrole were mixed with water and broadcast-sprayed on the surface. When herbicides were applied after planting, no effort was made to keep the spray off the dormant seedlings.

The 16 weed-control treatments were randomized in a complete block design that contained 4 blocks. Each treatment plot contained 10 rows of 10 trees or seed spots (one nut per spot) per row. A seedling of each species and a walnut seed were randomly assigned within each row. Thus, 40 seeds and 40 trees of each species were planted in each of the 16 weed-control treatments.

Spacing was 2 feet between and within rows.

Roots of all seedlings were pruned to 8 inches. Although seedling size varied among species, variation within a species was small. White oak and European alder, with top heights of 0.5 and 0.6 foot, respectively, were shortest. The tallest were river birch (1.5 feet) and American sycamore (1.4 feet). The other species' average heights ranged from 0.8 foot to 1.0 foot.

## RESULTS

The only treatment that completely controlled the weeds and grasses was cultivation. Herbicides controlled the competing vegetation in early summer, but their effectiveness had diminished by late September (table 1). Predominant among the late germinating competition found on the plots in the fall were giant foxtail (*Setaria faberia* Herrm.) and fall panicum (*Panicum dichotomiflorum* Michx.). All other major weeds observed were the perennials: gray goldenrod (*Solidago nemoralis* Ait.), trumpet-creeper, horsenettle (*Solanum carolinense* L.), and yellow nutgrass (*Cyperus esculentis* L.). Johnsongrass (*Sorghum halepense* L.) had invaded on a small portion of the area.

The effects of the various herbicide treatments on the survival and growth of individual species are discussed below.

*Black walnut seedlings.*--Neither survival nor growth was adversely affected by any of the weed control chemicals (table 2). This supports the findings of Erdmann (1967) who found that black walnut seedlings were not damaged by either simazine or atrazine. He did, however, caution that atrazine should not be applied on sandy soils because it is leached more rapidly and to greater depths than simazine. In a greenhouse study, Wichman and Byrnes (1971) showed that black walnut can tolerate as much as 1.00 ppm of simazine and is more tolerant of simazine than of atrazine or diuron. In a field

study, Roth (1971) observed slight damage to walnut seedlings from an 8 pounds-per-acre rate of simazine, while an 8 pounds-per-acre rate of atrazine caused severe damage. Black walnut seedlings normally grow little the first growing season after planting, so the poor height growth was not attributed to the weed control treatments.

*Black walnut seeds.*--Seed germination was poor but survival differences among treatments were not great (table 2). In a more recent study we found damage and mortality to germinating walnut seed when an atrazine-simazine mixture (2+2 pounds) was used.

*River birch.*--River birch was damaged by herbicide mixtures containing 2 pounds or more of atrazine (table 2). However, river birch seems tolerant of simazine, especially at low rates. Survival of seedlings treated with atrazine-simazine ranged from 92 to 42 percent, but when amitrole was the other chemical mixed with simazine, survival ranged from 100 to 82 percent. Cultivated trees were twice as tall as those treated with the highest rates of atrazine-simazine.

*Yellow-poplar.*--Survival of yellow-poplar decreased as the rate of herbicide was increased, regardless of the chemical used (table 2). However, survival was 80 percent or more except when the highest rates of atrazine-simazine were used; simazine was also a part of the amitrole-simazine mixture, so it appears that atrazine is responsible for poor survival. Height

growth of the cultivated trees was about double that of trees in herbicide-treated plots. These results for simazine and atrazine support the findings of Erdmann (1967). However, in their greenhouse study, Wichman and Byrnes (1971) found that yellow-poplar was very susceptible to damage by atrazine and only moderately tolerant of simazine.

*White oak.*--White oak appears to be tolerant of the chemicals at the rates used (table 2). Survival tended to be poorer when dichlobenil was used. Height growth, characteristically poor the first growing season, was poor for all treatments.

*Sweetgum.*--Sweetgum was tolerant of all chemicals, rates of application, and methods of application used. There were, however, small differences in height growth among the treatments.

*Sycamore.*--Survival of cultivated sycamore was 100 percent but 75 percent or less for all chemical treatments except dichlobenil (table 2). The extremely high mortality resulting from the chemical treatments other than dichlobenil shows the need for great caution when herbicides are tried. Height growth of cultivated sycamore was more than twice that of sycamore in any herbicide treatment.

*European alder.*--The survival of European alder was similar to that of sycamore: poor for all herbicides except dichlobenil (table 2). Survival of European alder was decreased more by atrazine-simazine applied after planting than to the same

chemicals applied before planting. Height growth of cultivated trees was best, but growth of some herbicide-treated trees was almost as good.

*Black locust.*--Survival of black locust was poor, 22 and 18 percent, when the atrazine-simazine mixture was applied at the highest rates (table 2). Survival was 90 percent or more in the dichlobenil plots. In plots treated with the amitrole-simazine mixture, survival was 82 percent or more for all but the highest rates. So, again, the more easily leached atrazine seems responsible for excessive mortality. Height growth for all treatments, except the two highest rates of atrazine-simazine, was good, but growth in the cultivated plots was far superior.

*White ash.*--Survival of white ash treated with dichlobenil was not correlated with rate. Survival was poor in plots treated with the 2+2 and 3+3 rates of the atrazine-simazine mixture and best for the two lower rates of amitrole-simazine (table 2). As noticed for other species, atrazine appears to be the harmful chemical. Although only 2.1 feet, height growth for the cultivation treatment was about double that for the best herbicide treatment and as much as seven times that of the poorest.

## DISCUSSION AND CONCLUSIONS

The lowest of the three herbicide rates used for each herbicide treatment was too low for adequate weed control. The highest of the three rates normally would be excessive. Under certain conditions, such as high temperature and dry soil, dichlobenil may volatilize, limiting effective weed control to about 2 months, thus allowing weed invasion for much of the growing season.

Many plant species are susceptible to chemical damage when very young, but are usually more tolerant of the same chemicals during the second or third growing seasons. Therefore, some of the species damaged by the herbicide treatments used in this study may show greater tolerance if the herbicide is applied after the first growing season. However, if herbicides are not used until the second year, weeds should be controlled by cultivation the first year.

Some species are much more susceptible to herbicide damage than others. Neither

black walnut nor sweetgum survival was affected by any of the herbicide treatments and only the highest rate of dichlobenil killed white oak. Survival of sycamore and European alder was decreased substantially by all herbicide treatments except dichlobenil. Survival of black locust, white ash, and river birch was poorest when mixtures containing atrazine were used.

Cultivation produced better height growth for most species than any of the herbicide treatments. Neither the growth of black walnut nor white oak was affected, but first-year growth of these two species is characteristically poor. Cultivated yellow-poplar, sycamore, black locust, and white ash grew much better than their chemically treated counterparts. Mixtures containing atrazine were especially detrimental to growth of river birch, sycamore, and European alder; sweetgum seems sensitive to dichlobenil.

With the exception of the poor survival of European alder when the atrazine-simazine mixture was applied after planting, it made no difference whether herbicides were applied before or after planting. Erdmann (1967), although testing other species, stated that atrazine should be applied before planting to prevent injury.

Each species was tolerant of at least one of the herbicides tested. Cultivated trees grew faster than herbicide-treated trees the first growing season, but cultivation is expensive. These results indicate, however, that for maximum growth some species should be cultivated the first year, then compatible herbicides used the second and third years.

## SEWAGE EFFLUENT SPRAY INCREASES DIAMETER GROWTH

### OF JACK PINE

ABSTRACT.--Sewage effluent applied to jack pine in southwestern Wisconsin significantly increased diameter growth during the second year.

OXFORD: 237.41:561.21:U628.38:174.7 *Pinus banksiana*. KEY WORDS: irrigated, sprinklers, dominant, increase, growth.

Only dominant and codominant trees were measured--14 on the 2-inch plot, 15 on the 4-inch plot, and 27 on the nonirrigated control plot. The trees were measured at the beginning and end of the 1974 growing season and at the end of the 1975 growing season. The data were tested for statistical significance by analysis of variance.

Sewage effluent was applied to forest land to determine how such irrigation might affect the growth of jack pine (*Pinus banksiana*, Lamb.). This note reports the results.

Average diameters, taken at the beginning of the study, were 9.6 inches for the control plot, 9.2 inches for the 2-inch application plot, and 8.7 inches for the 4-inch application plot.

### METHODS

The study site was located at the Fort (formerly Camp) McCoy military reservation in southwestern Wisconsin. The trees treated were part of a 45-year-old jack pine forest of medium stocking growing on the fast-draining Sparta sand. Until the early 1930's this land had been farmed.

Growing season rainfall was about the same for the 2 years (19.13 inches in 1974 and 20.06 inches in 1975). Normal rainfall for this period is 20.35 inches.

### RESULTS

Two plots of about 0.44 acres were established. One was irrigated and the other was not. The irrigated plot was divided in half, one half receiving 2 inches of effluent per week and one half receiving 4 inches per week. Effluent was applied throughout the year (intermittent during winter months) with 36 impact sprinklers situated to give equal distribution over the plots.

Diameter growth was not significantly affected by either application of effluent the first year. However, in the second year (1975) diameter growth was significantly greater (1 percent level) on both irrigated plots than on the control plot (fig. 1). Tree diameter did not influence growth response. The marked increase in growth the second year of irrigation suggests that waste water disposal on jack pine areas may produce a worthwhile benefit in increased wood production.

AN EASY-TO-MAKE SHELTER FOR THE TRIPLE BEAM  
BALANCE USED AT FIRE WEATHER STATIONS

ABSTRACT.--Describes how to build a housing for the balance used to weigh fuel moisture sticks. The housing is easy to build, low-cost, and can be mounted on the supports of the standard cotton region shelter.

OXFORD: 431.2--015.7. KEY WORDS: fire-danger-rating, fuel moisture sticks.

The National Fire Danger Rating System requires fuel and weather measurements to determine forest fire potential.<sup>1</sup> One of these measurements is the weight of fuel moisture sticks usually made with the aid of a triple beam balance. Unfortunately the balance is often housed in the cotton region instrument shelter or kept in the observer's office in lieu of constructing the somewhat elaborate, recommended balance-shelter. These practices can lead to serious measurement errors.

To reduce the chance for error, we have devised an inexpensive (about \$15)

housing for the balance that is easy to build and can be mounted on the supports of the cotton region instrument shelter (fig. 1). This design eliminates an additional installation and removes one possible shade source for the fuel moisture sticks. This balance housing can be made from 5/8-inch exterior plywood or 3/4-inch lumber. It has a plexiglas window across the front to facilitate readings on windy days (fig. 1).

The shelter is 36 inches long, 8 inches wide, and 10 inches high (fig. 2). Construct as follows:

1. Cut all wood parts.
2. Paint parts with an oil base primer.
3. Seal the predrilled plexiglas window on the inside with caulking compound and then screw it in place with #6 by 1/2-inch round head wood screws.
4. Glue and nail the box together with galvanized six penny box nails.
5. Finish with white exterior enamel house paint.
6. Attach brass hinges and hasp.
7. Bolt to instrument shelter supports in level position, facing south 4 inches below floor of instrument shelter (fig. 1).

**ABSTRACT.**--Plywood house siding made to simulate reverse board-and-batten design is sometimes attacked by woodpeckers because leaf-cutting bees, their prey, make nests in holes in the plywood core. The problem can be prevented by plugging the holes before nesting occurs. If nesting does occur, the nest should be destroyed and then the holes plugged.

**FOR:** 845.4:845.58. **KEY WORDS:** woodpeckers, plywood siding, leaf-cutting bees, bee nests.

Homeowners in wooded areas of southern Michigan have been experiencing damage to the rustic plywood wood siding on their houses. Woodpeckers had excavated at various places on their houses in search of prey, a leaf-cutting bee, *Megachile relativa* Cresson,<sup>1</sup> that had taken up residence inside the siding (fig. 1).

All houses attacked were sided with cedar or redwood exterior plywood constructed

Figure 1.--Holes in plywood siding caused by woodpeckers seeking megachilid bee larvae.

to simulate a reverse board-and-batten design. The design resembles 8 to 10 inch vertical rough-sawn boards, separated by spaces backed behind with batten boards. These spaces are actually grooves cut about half-way through the plywood, which may be 3/8 to 3/4 inch thick, depending upon the siding.

The woodpecker-bee problem arises because of factory plywood construction

<sup>1</sup> Specimens identified by R. L. Fischer, Department of Entomology Michigan State University, East Lansing, Michigan 48824.

procedures used in making the reverse board-and-batten design. The core veneer, or inner layers, used for plywood construction are assembled from lower quality veneer pieces of various widths. During assembly of the plywood sheets, gaps or small voids inevitably occur from place to place between the core layers. The face and back veneer ordinarily cover these voids, but they are sometimes visible on the edges. The voids do not affect the strength or appearance of the plywood. However, when the grooves are cut for the reverse board-and-batten effect, the voids are exposed. Megachilid bees seek out such small cavities to build their nests and enlarge them, if necessary, for cell construction. These cells, provided for the young bees, are lined and separated by circular pieces of leaf tissue. Six or more containing one larva each may be constructed in the cavity depending on its length. Thus, a nest may be 5 or 6 inches long.

Woodpeckers locate these nests and peck holes in the plywood to remove the larvae. The holes, up to 1/2 inch in diameter and 5 or 6 in a row at each attack, are jagged and contrast readily against the dark-stained wood.

This problem is probably rather common. Reverse board-and-batten plywood siding is popular and extensively used in wooded areas to provide a rustic look. *Megachile relativa* and woodpeckers both live in wooded areas and take advantage of this situation.

The problem can be prevented by sealing or plugging the exposed voids that appear in each of the grooves cut in veneer cores. This will eliminate the nesting sites. Sealing the voids at the factory could greatly increase the cost of the material, so the best method is for the on-site contractor or owner to check the plywood and plug or fill any holes present. These entrance holes must be filled before the bees build their nest. If the holes are plugged after the nest is made, the bees will chew their way out or the woodpeckers will seek out the larvae. The only recourse then is to destroy the nest with a long thin instrument, such as a stiff wire, before woodpeckers discover it. Holes already made by woodpeckers can be patched with an exterior patching compound stained to match the plywood finish. This is time consuming, however, and will show, so the preventive treatment is recommended.

## GROWTH OF RED PINE PLANTED ON A NORTHERN HARDWOOD SITE

Douglas M. Stone, Associate Silviculturist  
Northern Hardwoods Laboratory  
Marquette, Michigan

**ABSTRACT.**--A red pine conversion planting was established on a cutover northern hardwood site in 1929. Competing hardwoods were controlled on half the area by cleaning during the first 10 years after planting. After 46 growing seasons pine survival was 70 percent on the cleaned plot, and 25 percent on that not cleaned; mean annual increment was 2.37 cords (190 ft<sup>3</sup>), and 0.91 cords (73 ft<sup>3</sup>) per acre respectively. Merchantable volume of pine was 109 and 42 cords per acre. These data demonstrate the inability of red pine to compete with maple on medium textured soils, and illustrate the growth potential of the species if hardwood competition is controlled during plantation establishment. Results indicate that merchantable volume production on some well drained northern hardwood sites could be doubled by intensive management of red pine.

This paper documents the performance and competitive ability of red pine planted on a well drained northern hardwood site.

### METHODS

#### Stand and Site

The plantation is located on the Upper Peninsula Experimental Forest near Marquette, Michigan, 10 miles (16 km) south of Lake Superior. The area was originally occupied by virgin northern hardwoods, chiefly hard maple (*Acer saccharum* Marsh.) averaging about 14,000 board feet per acre (35,000 per ha). The original forest was commercially clearcut in 1920. In 1928 the area was described as "a very open stand of sugar maple and brush."<sup>1</sup> There is no evidence that the area had been burned.

OXFORD: 562.21:815:174.7 *Pinus resinosa*.  
KEY WORDS: red pine, species conversion, cleaning, hardwood competition, intensive silviculture, site quality.

The soil is a Munising sandy-loam, a weakly developed spodosol (Alfic Fragiorthod) formed in well drained acid till of Valders age. Most of the roots occur in the upper 15 inches (38 cm) of soil; pH averages 4.8. A fragipan 6 to 16 inches (15 to 40 cm) thick occurs at a depth of about 18 inches (46 cm). Nutrients in the upper 10 inches (25 cm) of soil average approximately 0.12 percent total N, 35 lb/acre (40 kg/ha) P (Bray P<sub>1</sub> extractable), 90 lb/acre (100 kg/ha) K, 960 lb/acre (1,075 kg/ha) Ca, and 112 lb/acre (125 kg/ha) Mg (NH<sub>4</sub>OAc extractable). This is a medium site

In the Lake States, natural stands of red pine (*Pinus resinosa* Ait.) typically occur on dry, sandy soils (Braun 1950). The species occurs only rarely on heavier soils, probably because it cannot compete successfully with more aggressive species (USDA For. Serv. 1965). The inability of planted red pine to endure inadequate aeration encountered on poorly drained, heavy soils is well established (Stone *et al.* 1954, Dreisinger *et al.* 1956).

<sup>1</sup> Unpublished data on file at the Northern Hardwoods Laboratory, Marquette, Michigan.

for growth of northern hardwoods: site index averages about 60 feet (18 m) at 50 years for sugar maple and 80 feet (24 m) for red pine.

### Plantation Establishment

Concern over the lack of adequate hardwood regeneration following clearcutting of the old growth timber prompted a series of trials "to test the possibilities of underplanting and conversion plantings on cutover hardwood lands."<sup>1</sup> The objective of the underplanting and supplementary plantings was to develop fully stocked, conifer-hardwood stands. The aim of the red pine conversion planting was to develop a pure pine stand by cleaning as necessary to free the pine from competing hardwoods. Significantly, only the conversion planting with the planned cleaning treatments has shown any degree of success.

The red pine was planted in May 1929 at a spacing of about 7 by 8 feet (2.1 by 2.4 m) "on open hardwood land covered with brush, grass, weeds, and scattered young hardwoods"<sup>1</sup> (fig. 1). Planting stock was 2-1-2 transplants from the Higgins Lake

Nursery in northern Lower Michigan. The plantation was first cleaned in August 1929. The subsequent records are fragmentary: as far as can be determined, the east half of the plantation was cleaned again the 3rd, 4th, and 6th years, and probably about the 10th year. The west half either was never cleaned, or was cleaned only the year it was planted.

At age 46 (from planting), diameter and merchantable height of all surviving pine were measured on a 0.1-acre (0.04 ha) plot in each half of the plantation (table 1).

### RESULTS

First-year survival of planted seedlings was 99 percent and height growth averaged 7 inches (17.8 cm). After five growing seasons survival was 94 percent, total height ranged up to 7.2 feet (2.2 m) and averaged 4.1 feet (1.25 m). At 9 years the largest pines measured 14 feet (4.3 m) and averaged 8.8 feet (2.7 m) in height, but survival had dropped to about 80 percent.

Over the next 37 years, adjacent hardwoods, primarily sugar maple, completely

<sup>1</sup> Bruno Lindfors, Munising Ranger District, Hiawatha National Forest, determined the merchantable volume of pine.

<sup>2</sup> Gross volume from composite volume table 6 (Gevorkiantz and Olson 1955).

<sup>3</sup> Net volume calculated at 80 cubic feet per rough cord.

replaced the planted pine on the south 33 feet (10 m) of the plantation, across both the cleaned and noncleaned portions. Hardwood encroachment also was severe along the west 20 feet (6 m) of the original planting. On the east side and along most of the north side of the plantation encroachment was negligible and pine survival was good. By 1974, 38 percent of the red pine in the cleaned half of the plantation were alive, but only 13 percent on the non-cleaned portion. Based on the two sample plots located in the areas of highest pine stocking, survival averaged about 70 percent in the cleaned portion, and 25 percent in that not cleaned. The larger dominant pines averaged 79 feet (24 m) at age 46.

## DISCUSSION

Early survival and growth were excellent for this region, probably due to a combination of site quality, careful planting, and use of large, vigorous planting stock. The transplants used in this study were older and presumably larger than the 3-0 red pine stock commonly used today. Unfortunately, no records are available on survival and growth after the 9th year. Apparently, most of the mortality occurred fairly early in the life

of the stand because height growth of the surviving pines has exceeded that of the adjacent hardwoods for many years and there is little evidence of recent mortality on the plots (fig. 2).

Despite good early survival and growth, many of the pines could not compete with the encroaching hardwoods. Survival probably would have been greater with an additional cleaning at a later age, particularly along the south side of the planting where the hardwood encroachment was most severe. Even in the interior of the plantation where survival was 70 percent, the cleaned plot contains 100 maple stems per acre (250/ha) 2.0 inches (5.0 cm) dbh and larger, and an understory of maple saplings 5 to 10 feet (1.5 to 3.0 m) in height persists. The pine probably cannot be regenerated naturally; even if the maple were eliminated by thorough site preparation, the development of grass, brush, and herbaceous competition on this site would undoubtedly preclude the establishment of red pine from seed (fig. 1).

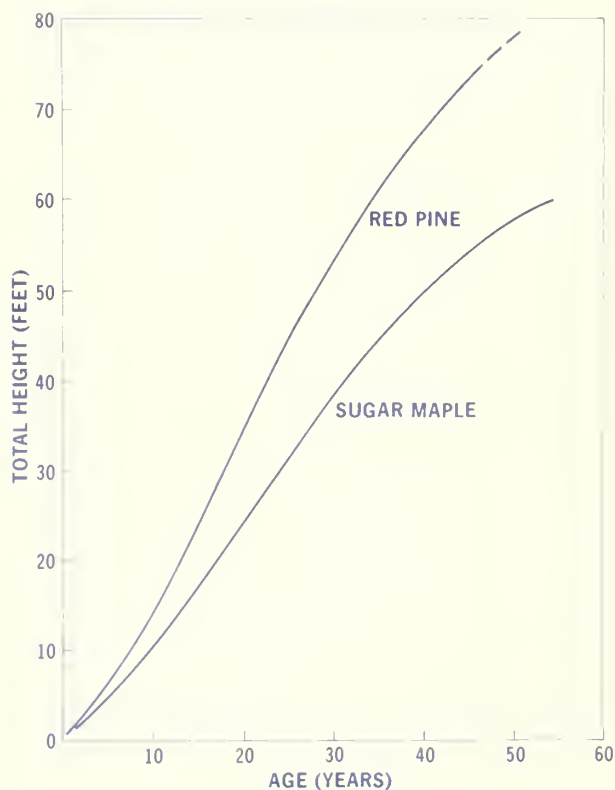

Figure 2.--Height growth of red pine 46 years after planting on a northern hardwood site, and 54-year-old sugar maple in the adjacent stand. Both curves based on codominant trees; site index (50 years) is about 60 for maple and 80 for red pine.

The poor survival in the noncleaned portion of the planting confirms the inability of red pine to compete with more aggressive species on medium textured soils (USDA For. Serv. 1965). Without the early cleanings, pine survival was only 13 percent over the entire area and 25 percent on the well stocked plot in the interior of the planting. Although the noncleaned plot contains more than 1½ times as many hardwoods as red pine, the pine has grown faster in both diameter and height than the hardwoods (table 1, fig. 2).

Volume growth of the red pine has been impressive, particularly on the cleaned plot. The mean annual increment of 2.37 cords per acre substantially exceeds published values for the species (Buckman 1962). In fact, growth of over 100 cords per acre in less than 50 years is high for any species in the Lake States (Horton and Bedell 1960, Wilde *et al.* 1965). The slightly lower average diameter of the pine on the cleaned plot reflects the excessively high stand density.

Mean annual growth on the cleaned plot has been 190 ft<sup>3</sup> per acre, more than 2½ times that on the noncleaned plot (table 1). A typical even-age northern hardwood stand nearby had a mean annual merchantable growth of 54 ft<sup>3</sup> per acre for 30 years after a commercial clearcut (Jacobs 1969). However, periodic annual growth from age 25 to 30 was 120 ft<sup>3</sup> per acre. Assuming that growth continues at this rate, at age 46 the hardwood stand will have a mean annual growth of 77 ft<sup>3</sup> per acre, about equal to that of the red pine on the noncleaned plot, but only about 40 percent of that on the cleaned plot.

This conversion planting has illustrated the inability of young red pine to compete with maple on a site where northern hardwoods are the climax vegetation. However, it also indicates the growth potential of red pine on an average, well drained northern hardwood site if maple competition is controlled during the first 10 years after planting.

These results indicate that the performance of red pine needs to be evaluated over a wider range of sites. In general, well stocked northern hardwood stands on medium and better sites contain many high quality stems and should be managed for high value products. However, many northern hardwood stands in the Lake States are below average in stocking, growth, and/or tree quality because of stand history, or

occasionally, site quality. The species occupying a given site do not necessarily indicate the maximum yield, in volume or value, attainable on that site. Stevens and Wertz (1971) for example, estimated a potential 60 percent increase in sawtimber yield by coordinating species distribution with soil productivity in northern Wisconsin.

Although it is impossible to extrapolate from a small, nonreplicated study, these data indicate that volume production may be doubled by intensive management of red pine on some well drained northern hardwood sites. If these sites are utilized to produce high value softwood products like poles, piling, and saw logs, rather than poor quality hardwood products, the value yield will be more than doubled.

PRELIMINARY BELT LIFE DATA FOR ABRASIVE PLANING OF PONDEROSA PINE

Harold A. Stewart, Forest Products Technologist, Forestry Sciences Laboratory, Carbondale, Illinois

ABSTRACT.--Initial observations indicate belt life may be longer and belt loading less at 0.080-inch than at 0.040-inch depth of cut with other machining variables held constant.

OXFORD: 823.1:829.13:174.7 Pinus ponderosa. KEY WORDS: machining, sanding, surfacing, tool life.

Abrasive planing is widely used to avoid knife planing defects when surfacing wood. More than 1/4 inch of stock can be removed by this method, but generally depth of cut averages less than 1/16 inch for hardwoods at 30 to 40 feet per minute and much less than 1/32 inch for softwoods at 90 feet per minute. Proponents of abrasive planing claim economic advantages without sufficient unit cost data. Belt life data for specific combinations of feed rate and depth of cut need to be developed for specific belt speeds before the real cost of removing stock by abrasive planing can be determined.

We do not yet know where studies of depth of cut and feed rates for abrasive planing belt life should begin. So, a short study was undertaken to help establish the initial combinations. Preliminary data indicate that unique factors influence tool life relations for abrasive planer belts and that comprehensive belt life studies will be required to accurately estimate the unit cost for abrasive planing

at specified feed rates and depths of cut within the ranges of current machinery.

METHODS

A sample of air-dry (12 percent average moisture content) nominal 2- by 4-inch ponderosa pine lumber was skip-dressed and then surfaced on both 4-inch faces to a uniform thickness so a uniform depth of cut could be maintained in the study. A resinous softwood was selected so that the belt life tests would go faster.

Three depths of cut (0.040, 0.080, and 0.120 inch) were applied to the lumber at a constant feed rate of 90 feet per minute and a nominal belt speed of 5,800 feet per minute. A new belt was used for each depth of cut, and the 4-inch-wide material was fed end-to-end until the belt failed.

RESULTS AND DISCUSSION

The 0.080-inch depth of cut resulted in the longest belt life:

Table with 3 columns: Depth of cut (inches), Belt life (feet), Total stock removal (cubic feet). Rows for 0.040, .080, and .120 inch depths.

Although the results are limited, the shorter belt life at the 0.040-inch depth of cut than at 0.080-inch depth of cut was surprising. Generally, belt life decreases as depth of cut or stock removal rate increases.

Two explanations are possible. First, the sample for the 0.040-inch depth of cut was at or near the lower tail of a belt life population and the sample for the 0.080-inch depth of cut was at or near the upper tail of a belt life population; and the two populations overlapped to some extent (fig. 1). Second, the belt from abrasive planing at 0.040-inch depth of cut was visibly more loaded with sanding particles than the other two belts (fig. 2). This may indicate that excessive belt loading reduces belt life for 0.040-inch depth of cut. Further, sample end points of belt life where the test results overlap could be misleading alone. Inspection of the belts is also required.

Figure 1.--Possible relation of belt life to depth of cut if a single sample at 0.040-inch depth of cut were near the bottom of the population range and a single sample at 0.080-inch depth of cut were near the top of the population range for respective machining situations.

The excessive loading of the belt at 0.040-inch depth of cut suggests a relation between sanding particle size and open space among the belt backing, grit, and workpiece when machining. Small particles from shallow depths of cut (approximately 0.015 inch or less) fit or are easily carried through the spaces formed by the belt backing, grit, and workpiece. At moderate depths of cut (such as 0.040 inch), the particles appear to be packed into the open spaces. At greater depths of cut (such as 0.080- and 0.120-inch) the sanding particles (chips) may be large enough to be forced ahead of the cutting tool (grit) and perhaps too large for the spaces. Thus, the large particles may create a wiping or cleaning action. Also, at the 0.120-inch depth of cut stresses and tool wear are much greater, thus reducing belt life.

High feed rates at slower belt speeds may prolong belt life. A long, thin particle could be "bunched up" to perhaps wipe or clean the belt similar to what happens with larger particles produced at depths of cut of 0.080-inch or greater. Another alternative would be to increase belt speed enough to approach a "zero" depth-of-cut condition. Actually, a wide selection of untried abrasive planing conditions may be as efficient or more efficient than present prescriptions.

Knots, because they cause instant power increases and, hence, stress increases, may have shortened belt life. The rapid stress increases would probably reduce belt life more at deeper cuts, such as at 0.080- and 0.120-inch, where the unit belt stress is higher initially. Thus, belt loading was apparently the major cause of short belt life at the 0.040-inch depth of cut.

Observations of commercial practice indicate the depth of cut for abrasive planing softwood lumber averages 0.010-inch with grit Nos. 24 and 36 at a feed rate of 90 feet per minute and belt speed at 5,800 feet per minute. Our preliminary tests indicate that abrasive planing at moderate depths of cut such as 0.040 inch may cause excessive belt loading and reduce belt life (fig. 3). The tests further indicate that heavy stock removal rates at depths of cut 0.080 or greater may reduce belt loading and prolong belt life. Thus, stock could probably be economically removed at other relative machining conditions. However, extensive tests will be required to determine the most efficient operating conditions for abrasive planing hardwoods and softwoods.

Figure 2.--No. 36 grit belt condition after machining ponderosa pine at 90 feet per minute feed rate and 5,800 feet per minute belt speed: (A) 0.040-inch depth of cut; (B) 0.080-inch depth of cut; (C) 0.120-inch depth of cut.

Figure 3.--Possible relation of belt life to depth of cut if a relation between sanding dust particle size and belt loading exists.

## PULPWOOD PRODUCTION IN THE LAKE STATES BY COUNTY, 1975

James E. Blyth, *Principal Market Analyst*

and Jerold T. Hahn, *Mensurationist*

**ABSTRACT.**--This 30th annual report shows 1975 pulpwood production by county and species group in Michigan, Minnesota, and Wisconsin. Production in these three Lake States fell to 4.1 million cords from 5.5 million cords in 1974.

**OXFORD:** 861.0(77):792. **KEY WORDS:** residue, Minnesota, Wisconsin, Michigan.

Pulpwood production in the Lake States plunged to 4.14 million cords in 1975 from 5.47 million cords in 1974 (table 1). Production dropped 562,000 cords in Michigan, 548,000 cords in Wisconsin, and 219,000 cords in Minnesota.

Most (92 percent) of the decline was in hardwood roundwood (including chips from roundwood). Half of the decrease was in aspen (669,000 cords). Other major declines were in maple (206,000 cords) and pine (116,000 cords).

About 89 out of every 100 cords were cut from roundwood (including chips from roundwood). The balance was derived from mill residue such as slabs, edgings, veneer cores, and chips from those materials.

Minnesota outproduced Michigan for the first time since 1958. However, Michigan's output was abnormally low because a major pulpmill was closed for several months while employees were on strike. In addition to the strike, a reduction in pulpwood inventories at some mills and weaker demand for paper and paperboard than in 1974 lowered Lake States pulpwood production in 1975.

Significant production declines occurred in Michigan's Upper Peninsula, northern and central Wisconsin, and northeastern Minnesota. Top-yielding counties were St. Louis, Koochiching, and Itasca in Minnesota; Oneida, Marinette, and Price in Wisconsin; and Iron, Menominee, and Delta in Michigan.

Pulpmills using Lake States timber in 1975 reported their pulpwood receipts by state, county, and species groups. Their cooperation is gratefully acknowledged. Thanks are also due the Michigan Department of Natural Resources for collecting the data from pulpmills in Michigan.

### EFFECT OF SUGAR MAPLE ROOT EXUDATE ON SEEDLINGS OF NORTHERN CONIFER SPECIES

Carl H. Tubbs, *Principal Physiologist*  
*Northern Hardwoods Laboratory*  
*Marquette, Michigan*

**ABSTRACT.**--It has previously been shown that a root exudate of sugar maple reduces the growth of yellow birch. A laboratory test indicated that the growth of northern conifers is also reduced in sugar maple root exudate. Allelopathy may play an important role in survival of species on sites where sugar maple is abundant.

OXFORD: 181.41:161.35:181.36:176.1 (*Acer saccharum*). KEY WORDS: allelopathy, *Acer saccharum* Marsh., *Betula alleghaniensis* Britton.

It has been previously shown that sugar maple seedlings are capable of inhibiting growth of yellow birch seedlings (Tubbs 1973) by means other than normal competition. When sugar maple leaves are mature, exudates from the growing roots reduce the growth of the roots of yellow birch. This is followed in turn by a reduction in the growth of birch stems. In nature, this limits the survival of yellow birch in northern hardwood stands.

Sugar maple ultimately invades many plant communities, both natural and planted. The purpose of the present experiment was to determine if some northern conifers, especially those with easily germinated seeds, are affected as yellow birch is.

#### METHODS

Dormant sugar maple seedlings were lifted from stands at the Upper Peninsula

Experimental Forest. Dormancy was broken by cold treatment and the seedlings were potted and grown in a greenhouse until the first leaves were fully expanded. Actively growing roots were then allowed to soak in distilled water for 48 hours in the dark at 41°F (5°C).

Four-tenths of a milliliter of the leachate was deposited on small steel planchets and evaporated to dryness.

Uniformly sized newly germinated seedlings<sup>1</sup> of black spruce (*Picea mariana* (Mill.) B.S.P.), tamarack (*Larix laricina* (DuRoi) K. Koch), jack pine (*Pinus banksiana* Lamb.), white spruce (*Picea glauca* (Moench) Voss), northern white-cedar (*Thuja occidentalis* L.), and yellow birch (*Betula alleghaniensis* Britton) were measured and placed on the planchets. Three milliliters of distilled water were added to each planchet (concentration of dry matter about  $4 \times 10^{-4}$  g/ml). The planchets were covered with plastic wrap and placed in covered glass dishes in the dark. Each dish contained all the species tested plus controls containing a seedling of each species to which only distilled water had been added. Each species was replicated eight times and there were four controls for each species.

The seedlings were allowed to grow 24 hours and were then remeasured. Comparisons

<sup>1</sup>Thanks are due to Wesley Lehmann of the Michigan Department of Natural Resources for the seed used in this experiment.

between controls and seedlings treated with maple root exudate were tested statistically by a "t" test.

## RESULTS

All of the species were repressed when growing in the maple root exudate. Northern white-cedar growth was highly variable both in water and exudate so that the differences in growth was not statistically significant. Tamarack was the most sensitive to the exudate; yellow birch and black spruce were least sensitive (table 1).

test plantings of jack pine, spruce, and tamarack on cleared sugar maple sites indicate that these species also grow well if growth is not impeded by competing sugar maple. Yellow birch seedling survival and growth is good where sugar maple has been eradicated but poor where sugar maple has not been eliminated from the stand (Tubbs and Metzger 1969).

Except for cedar, the species, tested here are thought to be relatively intolerant of shade, which helps explain why they do not commonly invade existing stands of tolerant sugar maple. But even when

Table 1.--Growth of newly germinated seedlings in sugar maple root exudate compared to growth in distilled water

\* Significantly different from control at 5 percent level or better.  
NS Nonsignificant.

## DISCUSSION

The inhibitory material in sugar maple exudate may be as important in determining what tree species will dominate after a disturbance in northern hardwood stands as condition of seedbed, seed production, and advance reproduction.

Most of the species in this test can grow very well on typical well drained sandy loam sugar maple sites, even though in nature they are usually confined to either excessively well drained soils (jack pine) or poorly drained soils (tamarack, black spruce, white spruce, northern white-cedar).

For them to do well, however, sugar maple seedlings and sprouts must be absent. For example, an unweeded red pine planting at the Upper Peninsula Experimental Forest died out while the weeded portion survived well and grew at a rate of over 2 cords per acre for 46 years.<sup>2</sup> Observations of small

light conditions are good for intolerant species, such as after clearcutting, there are fewer individuals of these species in the new stand than there are of the predominating sugar maple (Metzger and Tubbs 1971).

The reason that sugar maple is such a strong competitor in these cases seems at least partly due to its growth-inhibiting root exudate. Further field tests are needed with northern conifers to determine how important this inhibiting effect is in natural stands.

HYPOXYLON CANKER OF ASPEN

1976

ASSOCIATED WITH SAPERDA INORNATA GALLS

Neil A. Anderson, *Professor*  
*Department of Plant Pathology, University of Minnesota*

Michael E. Ostry, *Forestry Technician*  
*North Central Forest Experiment Station*

and Gerald W. Anderson, *formerly Principal Plant Pathologist*  
*North Central Forest Experiment Station*

*now Principal Plant Pathologist, Division of Forest Insect and Disease Research*

ABSTRACT.--Preliminary findings from a study to gain information on the infection process and genetics of resistance of the Hypoxylon canker fungus (Hypoxylon mammatum) on aspen (Populus tremuloides) indicate that the poplar-gall Saperda (Saperda inornata) may be involved. This paper describes the types of wounds made by the insect and how these and resulting Hypoxylon infections in the study plantation resemble the observed pattern of infections in the field.

OXFORD: 443:416.13. KEY WORDS: Populus tremuloides, poplar-gall Saperda, Hypoxylon mammatum, oviposition wounds.

Hypoxylon canker, caused by Hypoxylon mammatum Wahl. Mill., causes annual losses of more than 1 million cords of quaking aspen (Populus tremuloides Michx.) in Minnesota, Wisconsin, and Michigan (Anderson 1964). The means by which the fungus infects the tree is unknown and remains one of the major obstacles to the possible control of this disease.

In an attempt to gain information on the infection process and the genetical control of host resistance to this disease, three plantations consisting of aspen from controlled crosses have been established. These crosses involved parent trees that were cankered and noncankered and were selected over the geographic range of aspen in Minnesota. Beginning in 1966, crosses were made each spring and approximately 15 progenies plus the parents, established by root cuttings, were planted at 3 locations: Rosemount and Pike Bay, Minnesota,

and Langlade, Wisconsin. The results of the work at Rosemount, Minnesota, are reported here.

The plantation consists of 574 trees resulting from 41 different crosses. The trees were planted at a 10- by 10-foot spacing and now range in height from 4 to 25 feet. The nearest wild aspen stands are 0.5 and 2.3 miles from the plantation and only the latter stand contained some trees infected by H. mammatum. The plantation trees were observed each month throughout the growing season. So far, 13 Hypoxylon cankers have been positively identified. A Hypoxylon canker is considered "positive" when hyphal pegs releasing conidia or stroma-producing ascospores are found on a canker. All cankers were the result of natural infection and no artificial inoculation or wounding of any kind has been attempted.

All but one of the cankers was associated with an insect gall caused by Saperda inornata = (S. concolor). Manion (1975) also reported Hypoxylon cankers associated with this insect in New York. In several cases, hyphal pegs of the Hypoxylon fungus formed on the small branch near the gall. However, in most cases, the fungus produced spores after it had grown from the site of the gall down the branch and into the main stem of the tree.

The poplar-gall Saperda lays eggs in aspen branches usually less than 3/4 inch in diameter. Typical Cerambycid exit holes were noted on many galls. The branch is weakened at the site of the gall and is easily broken by the wind. The gall results from the deposition of eggs by the adult beetle and the subsequent development of the insect in the aspen branch. Shield- or u-shaped ovipositing scars are characteristic of this beetle. In the Rosemount plantation adult beetles emerged the first week of June, 1976, and at the same time hyphal pegs were being formed by the Hypoxylon fungus. The S. inornata infestation was first noted in August, 1973, on 1- to 3-year-old trees. These insect galls were the result of egg-laying activity the previous year.

Sixty additional "Hypoxylon-like cankers have begun at the insect galls and have as yet not produced spores typical of the Hypoxylon canker fungus. These cankers are similar to those reported by Nord and Knight (1972) which were also associated with S. inornata on aspen in Michigan. Several cankers have been noted resembling "Nectria" or "Ceratocystis" type cankers of aspen and these also appear to have begun in branch galls of this same insect.

The percentage of trees with positive Hypoxylon cankers is 2.26 and compares with infection data of aspen in natural stands. Many of the "Hypoxylon-like" branch cankers apparently will not migrate to the main stem as the branch often becomes too dry for fungus growth.

Since these observations were made on trees at the Rosemount, Minnesota, plantation, Hypoxylon cankers that appear to have started in S. inornata galls have been found on wild aspen trees in other areas of the State and also at the Langlade, Wisconsin, plantation.

The "typical Hypoxylon canker" with a central dead branch stub is a symptom familiar to foresters and researchers who have studied this disease. Also, it has been noted that, in general, the older the tree the higher the canker is on the main stem (Day and Strong 1959). Infection has long been suspected to have involved in some way the branch stub associated with most cankers.

Evidence from this study indicates that Hypoxylon infection can take place in insect galls on small branches or on main stems of small trees. The fungus grows down the branch and into the main stems and the branch is broken off at the gall resulting in the dead branch stub. While there are probably other means of infection, the one reported here associated with the S. inornata gall fits the pattern of Hypoxylon canker on aspen so commonly observed in Minnesota, Wisconsin, and Michigan.

Much remains to be learned about the infection process and the role of vectors in this insect-fungus-host relation. Also there are indications of insect resistance among the various aspen crosses. This type of resistance will be valuable in attempts to obtain insect and disease resistant aspen.

### THE IMPACT OF PULPWOOD RAIL FREIGHT COSTS ON THE MINNESOTA-WISCONSIN PULPWOOD MARKET

David C. Lothner, *Market Analyst*  
Duluth, Minnesota

**ABSTRACT.**--Transportation costs affect the marketing and utilization of pulpwood. Their impact on the procurement and utilization of pulpwood often prove difficult to measure because deriving an average annual measure of the transportation cost is difficult. This note, by means of a simple index method for measuring regional inter-State pulpwood rail freight costs, illustrates that the cost for shipping pulpwood from Minnesota to Wisconsin by rail more than doubled between 1946 and 1958. In 1959 rates declined slightly and remained stable before escalating in the late 1960's and early 1970's to more than three times the 1946 rate. Rail rates were estimated to have a significant impact on shipments of pulpwood from Minnesota to Wisconsin mills, and Wisconsin mill utilization of both softwood and hardwood pulpwood.

**OXFORD:** 783:717. **KEY WORDS:** pulpwood marketing, pulpwood freight rate index.

Because pulpwood is a bulky raw material with a low value-weight ratio, rail freight costs often account for a major portion of the total delivered cost of pulpwood to a mill. Even small changes in freight costs can affect mode of transportation, size and location of procurement areas, and kind of material used at the mill. So, measuring transportation costs is important to the industry as well as to economists attempting to analyze the behavior of pulpwood markets.

Unfortunately, it is difficult to derive an average annual measure of the cost of transportation. So we devised a simple index for measuring regional pulpwood rail freight costs and applied it to the Minnesota-to-Wisconsin inter-State pulpwood rail transportation cost trend. This enabled us to evaluate the influence of rail rates on the behavior of the Minnesota-Wisconsin pulpwood market.

The index is most useful when applied directly to regions where there is inter-State pulpwood traffic, i.e., where tariffs are governed by the Interstate Commerce Commission. Adjustments or changes in inter-State tariff schedules are nearly always percentage changes that apply across-the-board for all origin-destination points. This is not always the case with intra-State tariffs, where individual mills may negotiate rate changes with the railroads on pulpwood shipped over specific routes. Thus, in regions where intra-State rail shipments are common, the inter-State index may represent only an indication of the real cost relation.

#### CALCULATING THE INDEX

To calculate the index, first select a major pulpwood loading concentration point and pulpmill destination between which there are inter-State pulpwood shipments. Then obtain freight rate tariffs and their effective dates from the railroad moving pulpwood along the route. Next, multiply each

tariff rate by the number of months it was in effect during a specific year, add the products together, and divide by 12 to get an average tariff for each year. Finally, assuming the first year's tariff to be 100 percent, calculate the indexes for the subsequent years as percentage deviations from this "base" year.

### APPLYING THE INDEX TO MINNESOTA-WISCONSIN INTERSTATE PULPWOOD FREIGHT TARIFFS

Using the above procedure, we derived an index of inter-State pulpwood rail freight costs for Minnesota-to-Wisconsin shipments for the period 1946 to 1975 (fig. 1). It shows that the cost of shipping pulpwood by rail from Minnesota to Wisconsin more than doubled between 1946 and 1958. At that point changes in the tariff schedule were negotiated industry-wide and in 1959 the rates declined. Throughout most of the 1960's the rates remained stable before rapidly escalating in the late 1960's and early 1970's to more than three times the 1946 rate. Although published prices for pulpwood increased gradually throughout the major portion of the period (until the mid 1970's), transportation costs have represented an increasing share of the total cost of pulpwood to the mill.

Within both the Minnesota and Wisconsin hardwood pulpwood markets utilization of hardwood pulpwood has gained at the expense of softwood pulpwood since World War II. For example, the utilization of hardwood roundwood increased about 4-1/2 percent annually in both Minnesota and Wisconsin. Softwood roundwood utilization, on the other hand, decreased about 0.2 percent annually in Minnesota and 2.2 percent annually in Wisconsin.

Historically, Minnesota has been a primary pulpwood supplier for Wisconsin mills, and most of the shipments have been by rail in the last quarter century. However, pulpwood shipments from Minnesota to Wisconsin have decreased from approximately 400,000 cords during the early part of the period to just under 200,000 cords in 1973. The decrease in shipments in terms of total Minnesota production is even greater (fig. 2)

How are these trends related to pulpwood rail freight costs? In a recent study of the 1946 to 1969 period<sup>1</sup>, many Minnesota and Wisconsin pulp and paper mill officials cited changing transportation costs as a major reason for the increased importance

<sup>1</sup>Lothner, David C. 1974. *The Minnesota and Wisconsin pulpwood markets: and economic study of past changes and the future outlook for forest resource planning.* 215 p. Unpubl. Ph.D. Diss., Univ. Minn.

Figure 1.--Minnesota to Wisconsin inter-State roundwood pulpwood freight rate index, 1946 to 1975.

Figure 2.--The percent of Minnesota-produced roundwood pulpwood shipped to Wisconsin, 1946 to 1973.

of hardwood pulpwood, shifts in procurement areas, and the use of increased amounts of softwood *wood pulp* from outside the region. It was implied that mills often obtain more competitive rates on wood pulp from farther distances (outside the Lakes States region) than on pulpwood nearer the pulp mills.

A model of the Minnesota-Wisconsin pulpwood market was developed in which the rail freight index was one of several variables analyzed.

Increased rail rates, as indicated by the index, reduced Minnesota shipments of

pulpwood to Wisconsin mills: For every 1 percent increase in freight costs, Minnesota shipments of pulpwood to Wisconsin decreased by 0.75 percent, all other things remaining constant. Rail rate increases also decreased roundwood softwood utilization while increasing roundwood hardwood utilization by Wisconsin mills: for every 1 percent increase in freight costs the utilization of softwood roundwood pulpwood by Wisconsin's pulp mills decreased by 0.22 percent, all other things remaining constant, and the utilization of hardwood roundwood pulpwood by Wisconsin pulpmills increased by 1.07 percent.

## STEAMING CHIPS FACILITATES BARK REMOVAL

John R. Erickson, *formerly Principal Research Mechanical Engineer  
Forestry Engineering Laboratory, Houghton, Michigan  
now Principal Engineer, Forest Products and Engineering Research  
Washington, D.C.*

**ABSTRACT.**--Whole tree chipping is a productive and economical harvesting system. The resultant product, however, is barky chips. This paper outlines a promising method for removing the bark particles from whole tree chips.

**OXFORD:** 821:825.71. **KEY WORDS:** barking, whole tree chipping.

Logging residues in the United States total more than 3.5 billion cubic feet annually. Recovery of this valuable fiber could supply more than half our annual pulpwood requirements. These residues have not been utilized because of the high cost of harvesting by conventional logging methods and the lack of effective and economical methods for removing enough bark to make them suitable for pulping.

In general, the bark on most residues cannot be removed with conventional debarking methods. Most of the residues can, however, be chipped at reasonable cost if they can be concentrated at a central woods landing economically. We undertook some research to provide a means of removing bark after chipping.

We have published several articles on methods for removing bark from wood chips. This paper deals with a complementary process developed to increase the bark removal efficiency of the chip compression process (Arola and Erickson 1974). The improvement

includes steaming the unbarked chip mass before the compression treatment followed by a light mechanical attrition and screening.

### STUDY VARIABLES

The main variables considered for the chip debarking study were species, season chipped, steam pressure, and steaming time. Observations during testing indicated that we should also consider variation in bark removal and wood loss due to compression roll surfacing (smooth and knurled) and bark removal in each size class of chips.

In addition to steaming before debarking, we also submitted the output chips to a light mechanical attrition to break the bark remaining with the chips into fines. Mechanical attrition is beneficial because the bark remaining after compression is very friable and is readily subject to further breakdown. The selective breakdown in bark size allowed additional bark to be removed by screening. There are many attrition methods, so we decided to begin a new study dealing only with attrition methods. A separate report has been published on the results of that study (Mattson 1974).

Three major northern pulpwood species were tested; aspen (*Populus tremuloides*), sugar maple (*Acer saccharum*), and jack pine (*Pinus banksiana*).

Bark removal is affected by season of the year trees are cut and chipped: it is easier to debark during the growing season than during the dormant season. The efficiency of bark removal from chips also varies within season. So, over a 2-1/2-year period tests were made during several dormant and growing season months (table 1).

Table 1.--Cutting and chipping month schedule for bark removal tests

| Month     | Aspen | Jack pine | Sugar maple |
|-----------|-------|-----------|-------------|
| January   | X     |           |             |

#### TEST PROCEDURE

All material was cut in Baraga County and chipped at Michigan Technological University's Ford Forestry Center near L'Anse,

Michigan. The chipping was performed with a Morbark Chip Pac.<sup>1</sup>

After chipping, the sample material was brought to the Forest Engineering Laboratory in Houghton, Michigan. The barky chips were then screened using a Sweco Classifier<sup>1</sup> to remove fines (-3/16 inch) and oversized chips (+1-1/8 inch). The fines and overs were discarded. (In a mill situation the oversized material could be rechipped and recycled over the screens but they were discarded in these tests because a rechipper was not available.)

Next, the chips were steamed. Steam pressures and steaming times tried were 2 to 14 lb/in.<sup>2</sup>g and 1 to 10 minutes, respectively. Then chip mass was run through the compression debarker. Finally, the material was screened again to remove the waste and classify the chips by size.

#### RESULTS

Steaming the chips improved bark removal but adversely affected wood loss for all three species, but especially for aspen and sugar maple (tables 2 and 3).

<sup>1</sup>Mention of trade names does not constitute endorsement of the products by the USDA Forest Service.

Increased steam pressure seemed to improve bark removal in dormant wood, so we made further tests at higher pressures. Separate bark removal tests at 10 lb/in.<sup>2</sup>g

and 30 lb/in.<sup>2</sup>g were compared with tests run without steam treatment. The bark removal was significantly better as steam pressure increased (fig. 1).

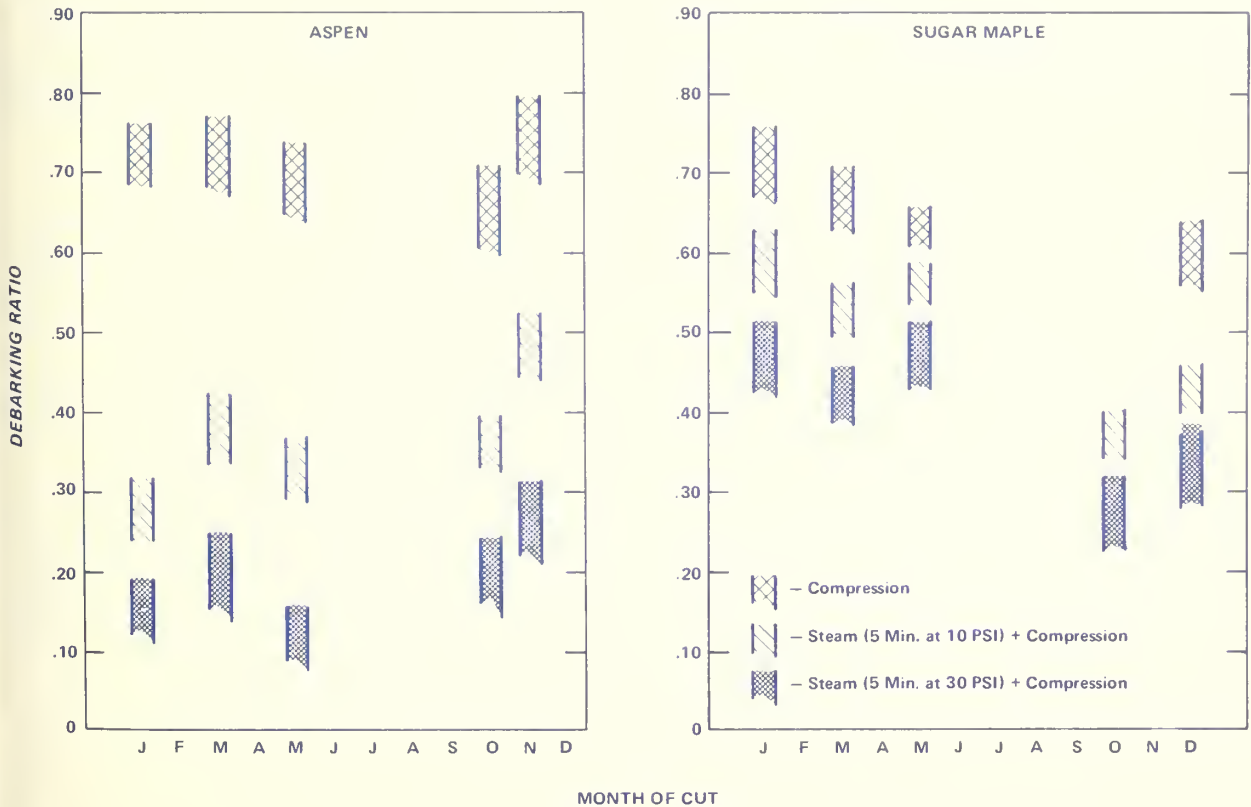

Figure 1.--The effect of chip steaming to improve bark removal with the compression debarking process.

Minimizing wood loss is important in any barking system, so an analysis was made of the wood loss along with the bark removal from the two different rolls--smooth and knurled. The knurled roll was used to ensure that the wood chips would be pulled through the nip spacing. It was found that the bark removal was nearly the same from both rolls while the wood loss in most cases was significantly greater from the knurled roll (table 4).

For all species the bark content in fractions exceeding a 3/8-inch round hole screen was very low (1 to 3 percent). The chips passing a 3/8-inch screen and held on a 3/16-inch screen (about 10 to 15 percent of the output) contained a considerable amount of bark. This 3/16-inch chip fraction can either be scalped for use as fuel or furnish for other lower grade fiber products, or processed further to remove more bark.

Table 4.--Bark removal and wood loss by roll surface  
(In percent)

| Species     | Growing season |           |              |           | Dormant season |           |              |           |
|-------------|----------------|-----------|--------------|-----------|----------------|-----------|--------------|-----------|
|             | Smooth roll    |           | Knurled roll |           | Smooth roll    |           | Knurled roll |           |
|             | Bark removed   | Wood loss | Bark removed | Wood loss | Bark removed   | Wood loss | Bark removed | Wood loss |
| Aspen       | 49             | 33        | 51           | 67        | 55             | 52        | 45           | 48        |
| Sugar maple | 42             | 5         | 58           | 95        | 47             | 28        | 53           | 72        |
| Jack pine   | 53             | 39        | 47           | 61        | 61             | 43        | 59           | 57        |

In view of these results, we decided to use two smooth rolls instead of one smooth and one knurled roll for future laboratory and pilot plant testing. To overcome feeding problems that can occur with some species, two smooth rolls with clearing slots machined the width of the roll have been tested with good results.

### TIMBER VOLUME IN IOWA COUNTIES

Arnold J. Ostrom, *Mensurationist*  
St. Paul, Minnesota

ABSTRACT.--The second forest inventory of Iowa shows timber volume reaching more than 1 billion cubic feet in 1974. Hardwoods make up 99 percent of this total.

OXFORD: 612(777). KEY WORDS: growing stock, sawtimber, hardwoods, softwoods.

Iowa's 1.5 million acres of commercial forest land supported more than 1 billion cubic feet in growing-stock trees in 1974. Included in the total volume of growing stock are 3.5 billion board feet of saw log material.

In addition, volume in live rough and rotten trees (nongrowing stock) is 308 million cubic feet.

Hardwoods completely dominate in Iowa, making up 99 percent of the total growing-stock volume. The oaks, led by white oak and northern red oak, make up almost 40 percent of the total. Other common species groups and their volumes are:

|            | <i>Million<br/>cubic<br/>feet</i> |
|------------|-----------------------------------|
| Oaks       | 403                               |
| Maples     | 148                               |
| Elms       | 95                                |
| Cottonwood | 92                                |

The State is divided into three geographical units--two in the east and one in the west. The northeastern and southeastern forest survey units contain the major concentrations of timber in the State (fig. 1). The three counties with the most growing-stock in the State are Allamakee, Clayton, and Jackson (table 1), all bordering the Mississippi River.

The sampling error of volume for the survey was  $\pm 3.96$  percent for 1,055 million cubic feet of growing stock in the State. The survey was conducted by the North Central Forest Experiment Station and the Iowa Conservation Commission.

### TALL FESCUE RESPONSE TO FIRE

George E. Probasco, *Associate Research Wildlife Biologist*  
Columbia, Missouri

and Ardell J. Bjugstad, *Supervisory Range Scientist*  
*Rocky Mountain Forest and Range Experiment Station*  
Rapid City, South Dakota

**ABSTRACT.**--Application of fire to tall fescue stands in the Ozarks caused significant changes in forage yields, seedstalk numbers, and stand composition.

**OXFORD:** 268.4:268.5(778). **KEY WORDS:** grass, grasslands, range management, pasture management, prescribed burning.

Converting tree and brush stands to tall fescue (*Festuca arundinaceae* Schreb.) grassland is common practice in the Ozarks (Crawford and Bjugstad 1967), but, maintenance of the grassland is hampered by invasion of woody plants. Fire has been used as a followup treatment to suppress top growth of woody plants in tall grass prairie (Kucera *et al.* 1963). Fire has also been used on native grassland to reduce competition from woody vegetation (Dalrymple 1969) and competition from undesirable bluegrass invasion (McMurphy and Anderson 1965). But the effect of fire on tall fescue in the Ozarks has not been investigated. So we designed a study to measure the response of tall fescue forage yields, seedstalk numbers, and stand composition to season of burning.

#### METHODS

A uniform tall fescue stand located on the Mark Twain grazing allotment on the Ava Ranger District of the Mark Twain National Forest in Missouri was subjected to

four different burning times (four applications) and a no-burn control. The burning times were: late winter (February) before dormancy of the vegetation was terminated; early spring (April) immediately after dormancy was terminated; midsummer (August) during the period when tall fescue is inactive; and late fall (November) just before the herbaceous vegetation becomes dormant. Dormancy here refers to the time when fescue is not actively growing because this species tends to remain green year-long. A control plot was mowed each time burning was done, so that burned and unburned stands could be compared. The burning times were selected to realistically represent management: they coincided with periods when both damage to the herbaceous vegetation and the time required for regrowth and return to grazing would be minimal.

Fire temperature was estimated by means of a graded series of thermal sensors (Probasco *et al.* 1976) to determine the temperatures associated with burning fescue stands and to find out if the temperature generated was above the minimum lethal threshold for woody vegetation. Byram (1958) reported that killing temperatures are time dependent. However, short-duration temperatures in the range of 60° C. to 65.6° C usually kill vegetation. Data were collected at 2.5 cm (1 inch) below the soil surface, at the soil surface, and at 5 cm (2 inches), 15 cm (6 inches), and 61 cm (24 inches) above the soil surface. The respective temperatures for the graded sen-

sors at each collection point were 37.8, 65.6, 149, and 232° C.

Forage yields were measured by the double-sampling technique (Wilm *et al.* 1944). Twenty 4.8 ft<sup>2</sup> quadrat samples were taken on each plot during June and October of the year following the burning.

## RESULTS AND DISCUSSION

The fire was consistently more intense at the midrange height, 5 cm to 15 cm (table 1). Intensity varied at the upper and

| 5                              | 100                     | 98   | 90  | 55  |
| 15                             | 98                      | 98   | 90  | 73  |
| 61                             | 100                     | 100  | 60  | 13  |

lower heights; greater intensity was attained at the lower heights early in the year and at the upper heights late in the year. The sensors set 2.5 cm below the soil surface were unaffected by the heat.

There were no significant differences in forage yields among the four treatments. However, tall fescue yields did differ significantly between burning treatments applied during the dormant or inactive growing period and those applied during active growing periods. Dormant burning did not reduce yield: yield averaged 3,083 lb/acre, which compares favorably to the 2,893 lb/acre produced on the unburned plots. However, burning during active growth significantly reduced production to 2,529 lb/acre.

Tall fescue seedstalk numbers were stimulated by the midsummer burn: numbers per square foot ranged from 8 for the early spring burn to 31 for the midsummer burn. Ehrenreich (1959) reported that similar treatments stimulates seed production of native grasses in Iowa.

Red clover (*Trifolium pratense* L.) was a rather insignificant component in the grass stand before the burns but increased substantially in plots burned in late winter or early spring (table 2).

After 1 year of study it appears that when burning only for tall fescue stand maintenance, fire should be applied during a dormant or inactive period, either late winter or midsummer. For renovating a red

<sup>2</sup>Letters denote no significant differences at 0.10 level based on standard analysis of variance techniques.

<sup>3</sup>Active growth period yields vs. inactive growth period yields were significantly different at the 0.10 level based on standard analysis of variance techniques.

clover stand, burn in either late winter or early spring. When considering both tall fescue and red clover, burn in late winter. When interested in tall fescue seed production, burn in midsummer.

Finally, a few precautions about the use of fire. Fire is an efficient and economical management tool, but its use calls for thorough planning and organization. Local fire authorities must be notified. Weather information, before, during, and immediately after the burn should be obtained. Adequate education as to the proper use and behavior of fire is also important to the success of any prescribed burn.

## WILDFIRE EFFECTS ON AN OAK-HICKORY FOREST IN SOUTHEAST MISSOURI

OFF. DOCUMENTS DEPOSITORY DIV.

Robert M. Loomis, *Fire Control Scientist*  
*East Lansing, Michigan*

CLEMSON UNIVERSITY LIBRARY

**ABSTRACT.**--Plant community development was observed for 10 years after a fire had top-killed most trees in a southeastern Missouri oak-hickory forest stand. The forest was re-established by sprouts. Production of herbaceous plants and other potential wildlife food was abundant for 4 years before decreasing to a stable preburn condition.

### THE STUDY

**OXFORD:** 435.1:434(778). **KEY WORDS:** plant succession, forest fire effects, wildlife food production, fire ecology.

The fire occurred May 7, 1966, in Iron County, Missouri, in a fully stocked stand of predominantly large saplings. The dominant stand was a 23-year-old white oak-red oak-hickory stand (stand type 52 as described by the Society of American Foresters (1954)), which had developed following a fire in 1943. The soil was a Clarksville cherty silt loam (Miller 1976)<sup>1</sup> with a site index of 70 for black oak (Schnur 1937). The slope averaged about 15 percent and had an easterly aspect. The fire top-killed almost all trees, but left a few 23-year-old survivors and some older trees that had also survived the earlier fire.

Many of the wildfires that occur in the North Central States burn oak-hickory forests. The amount of damage depends on the age and composition of the forest, the season of the burn, and the intensity of the fire. Sometimes only the ground vegetation or just the tops of the trees are killed, but other times the entire tree is killed. How a plant community responds after a fire would be useful knowledge for land managers to help them decide what action to take regarding salvaging timber, improving the stand, and providing food and habitat for wildlife. To find out how a stand did respond, the 10-year effects of a late spring fire on an oak-hickory community were studied.

Four plot point centers, three in the burned and one in the adjacent unburned area, were selected as representative of the area burned. Four sub-plots were located 7.9 m in cardinal directions from each plot center. The following information was gathered from each of the 16 sub-plots: (1) trees 1.5 cm dbh and larger that were intercepted using a 10-factor prism were tallied; (2) trees 30.5 cm or taller within a 4.6-m radius were tallied (height of only the tallest stem per single root system was measured, except after the 10th growing season when all heights were tallied); and (3) the annual production of trees, shrubs, vines, grasses, and forbs to a height of 1.5 m was estimated within 1.9 m<sup>2</sup>. Annual

<sup>1</sup>Miller, M. R. 1976. *Personal communication, Missouri National Forests.*

production for woody plants included the foliage and new stems or branches  $\leq 1.27$  cm in diameter; current growth on old stems or branches was not included.

Moisture content was determined gravimetrically at 85 C. The green weight estimates were converted to oven-dry.

Tree tallies were made 1, 2, 5, and 10 growing seasons after the 1966 fire, and production tallies were made 1, 2, 3, 4, 5, and 10 growing seasons after the fire. Estimates were made after major growth was completed--between mid-August and mid-October. The tree community was evaluated using the basic factors of frequency, density, and dominance--evaluation factors used by Curtis and McIntosh (1951).

## RESULTS

### Trees

The 1966 fire reduced the stand to 64 living stems and 1.1 m<sup>2</sup> of basal area per hectare. The surviving trees ranged from 10 to 46 cm dbh. Just before the 1966 fire, 79 percent of the stand was oaks and hickories (table 1). Surviving trees were almost all oaks.

The new tree stems developed primarily as basal sprouts of the top-killed trees. After the first growing season about 29,500 tree stems from 5,600 plants were growing per hectare. After 10 growing seasons the ratio had decreased from 5.3 stems per plant found the first year to 1.6 stems per plant. Height of the tallest stem for each plant for oaks, the major species, increased from 0.8 m after the first season to 2.9 m at the end of the fifth growing season. Following the 10th growing season when all stem heights were measured, heights for oaks averaged 6.3 m for the 8 cm dbh class, 5.9 m for the 5 cm class, 4.5 m for the 3 cm class, and 2.0 m for the less than 3 cm class. Oaks and hickories comprised 64 percent of the stand after 10 years (table 1).

Tree browse production reached a peak during the 3rd growing season (table 2), decreased markedly by the 5th growing season, and decreased further by the 10th growing season. Dogwood generally accounted for about one-half or more of the tree browse on the unburned area, and

<sup>2</sup>Convert kg/ha to lb/acre by multiplying by 0.892.

growing season there were still 3,500 *Rhus* and 1,200 *Corylus* stems per hectare.

Shrubs and vines provided the most abundant browse by the third growing season (table 2). Production decreased markedly by the fifth growing season.

#### Grasses and Sedges

Grasses and sedges were most productive the second and third seasons (table 2). They had decreased markedly by the 5th season, but did not change again by the 10th season. Grasses and sedges were sparse on the unburned area.

#### Forbs

Only 20 of the 34 forb genera identified on the burned plots after the first growing season remained after the 5th growing season and only 19 remained after the 10th. Only seven genera were found on the unburned plot. The high production of annuals such as *Acalypha*, *Ambrosia*, *Cassia*, *Croton*, and *Erechtites* during the first 2 years quickly became negligible.

The production of perennials such as *Aster*, *Cimicifuga*, *Desmodium*, *Galium*, *Monarda*, *Potentilla*, *Solidago*, and *Strophostyles* was high through the fourth season. Some production of perennials continued through the 10th growing season, but the plants were generally small and poorly developed. Five genera of perennials--*Aster*, *Desmodium*, *Galium*,

*Lespedeza*, and *Solidago*--were common on the unburned area.

Total forb production did not change the first three growing seasons (table 2). By the fifth season, production had greatly decreased but was stable.

Forb production was negligible on the unburned plot.

#### Deer and Turkey Food

Production of preferred deer and turkey foods were estimated on the basis of Murphy and Ehrenreich (1970). Peak production occurred the third season after fire for both of these game species foods (fig. 1). Production decreased sharply from the 3rd to the 5th season, and more slowly from the 5th to the 10th season. There was very little production of these preferred foods on the unburned area.

#### CONCLUSIONS

Top-killed trees of oak-hickory stands will usually re-establish themselves by sprouting. Thus, the major timber loss was 23 years of growth on the stand. To manage for optimum sawtimber volume and quality it would have been advisable to cut all residual trees because they tend to become large-crowned due to their dominant positions and produce low-quality sawtimber. They also suppress the new stand. But the scattered surviving trees are of special value for wildlife. Because these trees develop large crowns, they often

Figure 1.--Estimated production of preferred deer and turkey food for a burned and for an unburned oak-hickory stand in southeast Missouri. (Based on preferred foods lists presented by Murphy and Ehrenreich (1970).)

produce excellent nut crops. They are also potential den and nesting trees, provide different food, and lend esthetic diversity to the area.

Wildlife food was produced in large quantities for 4 years on the burned area. Thereafter, production greatly decreased, but it was still well above that on the unburned area.

Fire effects on an oak-hickory plant community should generally follow those observed in Iron County, Missouri. However, a similar fire may have different effects if the soil and site conditions, stand composition, age, or density are different. Whether effects of a fire in an oak-hickory stand are beneficial or destructive depends on the objectives and priorities of land management.

## INCREASING WHITE ASH SEED GERMINATION BY EMBRYO DISSECTION

OCT 20 1977

GLEASON

**ABSTRACT.**--Dissection of white ash embryos from the seed, coupled with cytokinin treatment, has been shown to enhance germination and seedling survival, as compared to whole seed stratification methods.

**OXFORD:** I61.6:176.1 *Fraxinus americana*.

**KEY WORDS:** zeatin, stratification, viability, yield, treatment.

A major barrier to the mass production of some forest trees is seed dormancy. Dormancy may be imposed by mechanisms ranging from impermeable seed coats to hormonal inhibitors (Leopold and Kriedemann 1975). Once the dormancy mechanism is known for a particular species, it can be circumvented, often by mimicking some environmental influence. In the laboratory, dormancy can often be broken with growth stimulants.

Seeds of white ash (*Fraxinus americana* L.) normally are dormant after imbibition (Mayer and Poljakoff-Mayber 1963). Sondheimer *et al.* (1968) demonstrated that dormant seeds of this species contain high concentrations of the potent germination inhibitor, abscisic acid (ABA), in both the embryo and endosperm. Stratification can break dormancy in white ash seeds, apparently both by reducing the ABA level

(Sondheimer *et al.* 1968) and by stimulating the appearance of growth stimulators (Villiers and Wareing 1965), probably hormones, in the embryo. On the other hand Sondheimer and Galson (1966) and Tzou *et al.* (1973) have induced dormant ash embryos (not stratified) to germinate by treating them with hormones (especially gibberellins and cytokinins). However, at best only about 30 percent of the seeds can be induced to germinate by either of these methods (McBride and Dickson 1972).

We used this information to design a system for germinating large numbers of ash embryos. We found that removing the embryos from the seeds and treating them with growth hormones gives much higher germination rates than conventional seed handling techniques.

### METHODS

#### Seed Viability

About 400 seeds were sliced longitudinally and placed in a 1 mg/ml solution of tetrazolium red in 0.1 M phosphate buffer, pH 7.0 for 6 hours. Viable embryos were stained red (Burstone 1962). Nearly 97 percent of the seeds were viable. Several imbibing techniques were employed (including a cold treatment) but no difference in apparent viability was found.

## Embryo Germination

Preliminary germination tests were carried out with several hormones, to find the best germination stimulator. Embryos were treated with zeatin, kinetin, and gibberellic acid, at concentrations reported by Sondheimer and Galson (1966), and Tzou, *et al.* (1973) to be effective in promoting germination of white ash seeds. Test procedures was as follows.

Winged seeds showing no insect damage were collected from several trees. The seeds were soaked in water for 24 hours, removed from the wings, and soaked for an additional 48 hours. The embryos were carefully dissected from the endosperm. They were placed in petri dishes, on filter paper soaked with hormone solution prepared in 0.01 M potassium phosphate buffer, pH 6.0, 10 embryos per dish. The dishes were then kept either in a growth chamber with a 17-hour day, or in a greenhouse with continuous illumination provided by supplemental fluorescent lighting.

After 10 days the germination rate was determined, and germinated embryos were transplanted to sand in styrofoam cups, which were capped with petri dish covers to prevent dessication. The survival rate was recorded at 13 days and again at 30 days after the start of the experiment.

A major factor reducing viability in the embryos was damage inflicted during dissection. Damaged embryos rapidly become necrotic and failed to germinate.

Only zeatin proved effective in stimulating ash embryo germination (fig. 1). Based on this result, extensive tests were done on germination and survival rates of ash embryos with zeatin.

### Stratification

Seed was planted in moist sand, placed in an incubator (68-78°F) for 30 days, transferred to a cooler (38°F) for 30 days, then allowed to germinate in an incubator for 60 days. Germination counts were made every two days.

## RESULTS

The results (table 1) show that the embryo dissection technique can lead to much

Figure 1.--Results of preliminary germination tests with several hormones. Error bars are two standard deviations.

greater germination than can stratification methods. Comparing germination and survival rates of hormone-treated embryos with those for untreated embryos in the two growth conditions indicates that environment may influence germination rates. Under the conditions used, continuous light appeared to produce much the same effect as the zeatin treatment. Apparently the environment also interacts with the genome of the seedling. The zeatin-treated embryos of the tree #13 had a low survival rate in the greenhouse, but not in the growth room; while the situation is reversed for the seeds of tree #14.

At the end of the 30-day growth period in sand in styrofoam cups, all the surviving trees were well developed and growing vigorously. They had one to two sets of true leaves and extensive root systems. The overall length of the plants from the various treatments was not significantly different. The mean length was 62.3 mm (S.E. = 4.15). These trees could be transplanted to soil and raised to maturity.

## DISCUSSION

The embryo dissection technique appears to be a valuable tool to circumvent the problems of germinating dormant ash seeds.

Table 1.--Results of germination tests on zeatin treated (+Z) control (H<sub>2</sub>O) embryos and whole seed stratification. The embryo method is based on 12 observations from 4 trees and 3 dishes. Stratification results are from 400 seeds per tree.

| s $\bar{x}$ | .8         | 7.6              | 5.6 | 6.9              | .8          | 12.7             | 5.8 | 12.7             | 13                         |

Survival rates above 90 percent are 2 to 3 times greater than obtained by stratifying and planting whole seeds.

This technique may be useful for selecting desired seedling phenotypes. Light and/or temperature conditions can be altered to select seedlings with increased chances of survival in particular natural conditions. In addition, the high rates of survival help to maximize yields when the number of seeds is limited, such as controlled crosses of particularly desirable seed parents.

In general, this technique provides a rapid and reliable method to obtain ash seedlings at a much higher yield than has been previously possible.

SLUDGE-TREATED COAL MINE SPOILS INCREASE  
HEAVY METALS IN COVER CROPS

- F. D. McBride, *Forestry Technician, Carbondale, Illinois*

ABSTRACT.--Four species of forage were grown in a greenhouse on acid strip mine spoil treated with municipal sewage sludge. Foliar levels of heavy metals exceeded those recommended for animal consumption. No plant toxicity symptoms were evident.

Kunkle 1973). Greenhouse tests of higher dosage rates were begun in 1972 for evaluation of the chemical changes in percolating subsoil water (Cunningham, R. *et al.* 1975).

OXFORD: 114.449.8U628.36:114.26. KEY WORDS: cadmium, strip-mine, reclamation, forage, sewage.

Tests of plant growth on agricultural soils that have received high dosages of sewage sludge indicate the need to maintain high pH values to reduce toxicity of metals on test plants. Suggested limits for total metal additions to soils, with a cation exchange capacity (CEC) greater than 15 m.e./100 g, are: Zinc 870 kg/ha, Copper 435 kg/ha, Cadmium 17 kg/ha (Sommers and Nelson 1976).

Acid spoil banks resulting from strip-mining of coal pose a severe rehabilitation problem because of toxic concentrations of cations and droughty surface soils. Digested sewage sludge has been used as one means of creating a medium for establishing plant growth in Ohio, Pennsylvania, and Illinois. In Illinois, research has been conducted by the USDA Forest Service on the Palzo tract of the Shawnee National Forest near Crab Orchard, representative of about 4,900 ha of the highly acid spoil conditions in Illinois (Haynes and Klimstra 1975). Rehabilitation plans have been developed cooperatively with the Metropolitan Sanitary District of Greater Chicago to use liquid sludge on about 73 ha of nonvegetated land (Cunningham, R. *et al.* 1975).

The use of sewage sludge for amelioration of phytotoxic conditions on acid spoils requires high dosages to alleviate acidity and reduce drought stresses, but is justified on highly acid spoil where the availability of micro-elements to plants might be expected to exceed plant tolerance limits.

COVER CROP TESTS

Preliminary field studies of the ameliorating effects of sludge on acid mine spoil showed that lasting effects required at least 178 metric tons/ha for continued growth of test vegetation (Lejcher and

Greenhouse tests were conducted in 30.5 x 60.5 x 122 cm deep leaching chambers by the North Central Forest Experiment Station at Carbondale, Illinois. Dosages of 336 and 672 t/ha dry weight equivalent of sewage sludge were incorporated into the surface 12.5 cm of spoil to simulate field procedure. Lime was added at 0,

22.4, and 44.8 mt/ha rates with two replicate chambers for each treatment combination. Dosage rates of nutrients and metals in the sludge are listed below:

| Sludge application rate t/ha | 336                | 672   |
|------------------------------|--------------------|-------|
| Element                      | Loading rate kg/ha |       |
| N                            | 7280               | 14560 |
| P                            | 6160               | 12320 |
| K                            | 1300               | 2600  |
| Ca                           | 11760              | 23520 |
| Mg                           | 4640               | 9280  |
| S                            | 4370               | 8740  |
| Fe                           | 18140              | 36270 |
| Cu                           | 250                | 500   |
| Cr                           | 1680               | 3360  |
| Cd                           | 70                 | 140   |
| Pb                           | 770                | 1540  |
| Ni                           | 17                 | 34    |
| Zn                           | 1144               | 2287  |

The sludge-treated chambers were leached with distilled water semi-monthly for 20 months. Percolating water was collected for analysis on a monthly basis. Results of analysis of this leachate are reported elsewhere (Cunningham, R. *et al.* 1975).

Four species of forage were planted at two planting dates in the leaching chambers according to the following schedule:

| Species           | Date planted | Date harvested |         |        |
|-------------------|--------------|----------------|---------|--------|
|                   |              | 1              | 2       | 3      |
| Rye (grain)       | 5/08/74      | 6/06/74        |         |        |
| Ky-31 Tall Fescue | 6/10/74      | 1/02/75        | 3/31/75 | 6/3/75 |
| Reed Canary Grass | 5/08/74      | 7/22/74        |         |        |
| Sudan Grass       | 10/18/74     | 1/22/75        | 3/31/75 | 6/3/75 |

The 12 replicates of each sludge treatment were equally divided between the two species planted on each date. Three lime treatments were superimposed. The six chambers planted to rye were replanted to tall fescue after the rye was harvested. The chambers planted to reed canary grass were replanted to sudan grass. Three clippings from the second set of species were harvested on the dates shown.

Foliage was clipped about 2 cm above the soil surface. Root systems were pulled out, washed thoroughly with distilled water, and dried and weighed. Vegetation samples were dried to constant weight, weighed, and ground for analysis. Vegetative materials

were analyzed at the Agronomy Lab, University of Illinois.

## METHODS OF ANALYSIS OF PLANT TISSUE

Plant tissues were wet-ashed in Folin-Wu tubes using a 10 ml mixture of 5:1 HNO<sub>3</sub>:HClO<sub>4</sub>. The ashed samples were then analyzed for Ca, Mn, Zn, Cd, Cr, and Cu by atomic absorption with background correction for matrix effects. Total nitrogen analysis was done according to the procedure of Bremner (1965).

## RESULTS

Application of sludge increased the cation exchange capacity of the soil (table 1). Peterson and Gschwind (1972) reported a CEC of Chicago sludge of 73 meq/100 g solids. pH values were increased by sludge applications. Reductions in acidity were measurable only to about 30 cm depths.

Table 1.--Cation exchange capacity and pH of the spoil profile of the sludge-lime treatments<sup>1</sup>

| Spoil depth : | Sludge application rates mt/ha |         |         |
|---------------|--------------------------------|---------|---------|
|               | 0                              | 332     | 664     |
| 0-7.5 cm      |                                |         |         |
| CEC           | 15-20 meq/100g                 | 20-29   | 27-40   |

| pH            | 2.7-2.9                        | 2.8-2.9 | 3.0-3.1 |

<sup>1</sup>Spindler, Dean R. 1976. Fate and effects of sewage sludge and lime on chemical characteristics of acid strip mine spoils. Unpublished M.S. thesis. Southern Illinois Univ., Carbondale, Illinois.

Concentrations of various nutrient elements are shown in table 2 for foliage and roots. Root systems extended to the depth of sludge incorporation, 12.5 cm. Root systems were generally higher in all trace metals except Mn than foliage. In general, higher dry matter production occurred on the 664 mt/ha treatment.

Sudan grass was a high accumulator of cadmium, especially at the high lime rates (table 3). Reed canary grass also accumulated cadmium at higher concentrations than

Table 2.--Nutrient content of foliage and roots of forage crops grown on sludge amended spoils

rye or fescue. Selection of these two forage crops for erosion control would also serve to retain metals on the site in the organic matter portion of the soil. Green manure management of sudan grass and reed canary grass would serve as an excellent method of holding cadmium in the surface soil to protect against leaching to ground water.

Zinc concentrations in foliage were consistently reduced by higher lime rates. Cadmium concentrations showed no consistent relation to liming, except in sudan grass. The highest cadmium levels occurred at 332 mt/ha sludge treatment and 0 mt/ha lime rate. It is also interesting to note that uptake of cadmium by sudan grass, and to

some extent by rye grass, always occurred at low sludge and lime treatment. This seems to indicate that the source of cadmium uptake is that which is indigenously present in the spoil materials. Laboratory analysis of spoils and roof shales from the area indicated the presence of sphalerite, a zinc sulfide ore, with cadmium sulfide as co-deposits. This explains why uptake of zinc is always high at low lime and low sludge treatments.

Nitrogen levels in both foliage and roots were highest in the high (664 t/ha) sludge rate for each species.

Zinc and cadmium levels were comparable to those reported by Jones *et al.* (1975) on agricultural soils treated with sludge at similar rates. King and Morris (1972) found that liming reduced the concentrations of Mn, Cu, and Zn in rye foliage where natural soils were fertilized with high rates of sludge. On the acid spoils liming reduced Zn and Mn consistently but Cu was erratically affected. Yields tended to be reduced by high lime rates in soils treated with 664 mt/ha of sludge (significant from 0, 332). This is probably due to the catalytic effect of high pH on oxidation of pyrite which is resulted from higher rate of ferric (Fe III) formation (Singer 1970).

Repeated cropping by the same crop would be required to determine the trend in metal concentrations.

<sup>1</sup>First crop on chamber.

<sup>2</sup>Second crop on chamber, mean of 3 clippings.

Leaching chambers not treated with sludge failed to produce any vegetative material for analysis. Lime treatments did not produce conditions amenable to growth of grasses without addition of sludge.

In selecting the best erosion control cover for the Palzo rehabilitation project, drought resistance must be considered as well as the factors discussed here. Rye offers the opportunity for dormant season cover as well as the lowest cadmium concentration in the foliage. A more drought-resistant species will be needed to maintain adequate ground cover during the summer months.

If a forage crop were to be selected for animal fodder on the basis of foliar cadmium concentration, rye would be the best choice although the levels are higher than those recommended for animal consumption (Melsted 1973). Although the two sludge rates were excessive in agricultural terms, crops did not show toxicity symptoms. If the use of the vegetation is to be limited to erosion control, reed canary grass offers the best trace element accumulation in the plant materials. Cadmium, zinc, and copper incorporated into plant tissues would be, at least temporarily, withheld from leaching to ground water or moving to streams by surface runoff.

### JACK PINE AND ASPEN FOREST FLOORS IN NORTHEASTERN MINNESOTA

Robert M. Loomis, *Fire Control Scientist*  
East Lansing, Michigan

CLEMSON  
LIBRARY

ABSTRACT.--Characteristics of upland forest floors under mature jack pine and aspen in northeastern Minnesota were investigated. These fuel measurements were needed as input for fire behavior prediction models--useful for fire management decisions. The forest floor weight averaged 33,955 kg/ha and depth averaged 7.1 cm. Bulk density averaged 17 kg/m<sup>3</sup> for the L (litter) layer, 45.7 kg/m<sup>3</sup> for the F (fermentation) layer, and 61.6 kg/m<sup>3</sup> for the H (humus) layer. The L layer was found to consist of 65 percent foliage, 31 percent wood and bark, 2 percent herbaceous vegetation, and 2 percent miscellaneous. No significant differences were found in weight, depth, or bulk density, except for the bulk density of the H layer, between the forest floors of jack pine and aspen.

OXFORD: 431.2(776) KEY WORDS: forest fuels, forest fire, fuel models.

Rothermel (1972) developed a fire behavior prediction model that is used for fire management decisions. To apply this model to the mature and overmature jack pine and aspen stands in the Boundary Waters Canoe Area (BWCA) of the Superior National Forest, it was necessary to determine the characteristics of the forest floor. Reported here are the weight, depth, and bulk density of the forest floor under these stands.

#### THE STUDY

Fifteen 0.2 hectare plots in mature jack pine and aspen stands were selected on the Kawishiwi Ranger District of the Superior National Forest in Lake County, Minnesota. These plots were representative of much of the area in the BWCA and showed no evidence of fire within the past 30 years. The stands were on gently rolling topography with shallow sandy loam soils and an occasional exposure of bedrock. Both the jack pine and the aspen stands were similar in age, basal area, and number of trees per hectare (Table 1). Field collections were made from late June through July 1976.

For each plot, 64 uniformly distributed, 12.7 cm diameter circular subsamples were selected to determine the estimated mean weight per hectare of forest floor materials. The estimated weights were determined from initial plots to be within 12 percent of the mean for the L layer, 13 percent of the mean for the F layer, and 17 percent of the mean for the H layer, all with 95 percent confidence limits. Similar material from all subsamples in a plot was then pooled for processing. All sample material was oven-dried at 105 C. In addition, the H layer material was ashed in a muffle furnace at 590 C. The reported H layer weight is the loss by incineration. This procedure eliminated both mineral soil and ash from H layer weight. Cones, wood,

<sup>3</sup>Multiply no/ha by 0.405 to convert to no/acre.

and roots larger than 0.6 cm in diameter or thickness were excluded from the samples. Depth measurements were made at each of the 64 subsample points using the profile exposed by removing the forest floor material. Distinct separation of the forest floor layers was often difficult because there was a gradual rather than an abrupt transition. The most troublesome separation was between humus and mineral soil because a duff mull profile, that includes an A<sub>1</sub> horizon, was present occasionally. The top of the L layer was defined as the highest forest floor particle within 2.5 cm of the point where the profile was measured.

## RESULTS

Total weight of forest floor in these stands averaged 33,955 kg/ha of which 2,937 kg/ha was litter (L) layer, 6,860 kg/ha was

the fermentation (F) layer, and 24,158 kg/ha was the humus (H) layer. Forest floor total depth averaged 7.1 cm of which about one-fourth was litter. Bulk density averaged 17.0, 45.7, 61.6 kg/m<sup>3</sup> for the L, F, and H layers; respectively (Table 2).

By weight, the L layer contained 65 percent foliage (leaves and/or needles), 31 percent wood (twigs, bark), 2 percent herbaceous vegetation and 2 percent miscellaneous (small cones, flower parts, etc.).

Except for H layer bulk density, there were no significant differences (0.05 level) between the jack pine and aspen stands for weight, depth, or bulk density for any forest floor layer. Thus, all plots were combined. An average of 55 percent of H layer oven-dry weight was subtracted as ash and soil.

<sup>1</sup>Cover types as described by Society of American Foresters (1954).

<sup>2</sup>All weights are oven-dry; H layer weight is weight loss due to incineration; multiply kg/ha by 0.892 to convert to lb/acre.

<sup>3</sup>L layer depth measured from tip of highest leaf, needle, or twig; multiply cm by 0.393 to convert to in.

<sup>4</sup>Multiply kg/m<sup>3</sup> by 100 to convert to kg/ha/cm; multiply kg/m<sup>3</sup> by 0.062 to convert to lb/ft<sup>3</sup>.

## DISCUSSION

Normally a moisture gradient exists in the forest floor with moisture increasing with depth. This, together with increased bulk density, decreasing volatile content, and increasing ash and mineral content with depth, helps explain why forest floors resist complete consumption from fires. Even a high-intensity fire rarely consumes more than the L and F layers.

These weight estimates are for summer conditions. The L layer is the more responsive to seasonal changes; maximum amount is present after autumn leaf fall (Blow 1955, Loomis 1975) and minimum amount is present just before autumn leaf fall. The difference between maximum and minimum L layer forest floor weight would be approximately equal to annual litter production. Grigal and McColl (1975) reported total litter fall of 1,139 kg/ha/yr under northeastern Minnesota upland mature stands similar to those we studied but with a basal area of only 12.8 m<sup>2</sup>/ha compared to the basal area of 18 m<sup>2</sup>/ha of our plots. A general relation between annual litter production and latitude as presented by Bray and Gorham (1964) suggests that about

3,360 kg/ha/yr is produced. Litterfall was not measured in this study.

## PULPWOOD PRODUCTION IN THE LAKE STATES

1977

### BY COUNTY, 1976

James E. Blythe, *Principal Market Analyst*

and Jerold T. Hahn, *Measurementist*

**ABSTRACT.**--This 31st annual report shows 1976 pulpwood production by county and species group in Michigan, Minnesota, and Wisconsin. Production in these three Lake States climbed to 4.7 million cords from 4.1 million cords in 1975.

**OXFORD:** 861.0(77):792. **KEY WORDS:** residue, Minnesota, Wisconsin, Michigan.

Lake States pulpwood production rose to 4.69 million cords in 1976 from 4.14 million cords in 1975. Production increased 22 percent in Wisconsin to 1.84 million cords and 20 percent in Michigan to 1.54 million cords. Output in Minnesota fell 4 percent to 1.31 million cords.

Nine out of 10 cords were cut from roundwood, including chips from roundwood (table 1). The remainder was derived from mill residue such as slabs, edgings, veneer cores, and chips from those materials. Production from softwood and hardwood residue by State was:

| State     | Softwood               | Hardwood |
|-----------|------------------------|----------|
|           | Hundred standard cords |          |
| Michigan  | 243                    | 1641     |
| Minnesota | 335                    | 658      |
| Wisconsin | 384                    | 1291     |

All the increased output was from roundwood; use of Lake States wood residue for pulp fell slightly. Major increases from roundwood were in aspen (218,000 cords), elm (166,000 cords), birch (74,000 cords), pine (66,000 cords), and maple (61,000 cords). The continuing spread of Dutch Elm disease led to more than a 3-fold increase in elm harvesting for pulpwood; Wisconsin supplied 85 percent.

Increased harvesting occurred primarily in Michigan's Upper Peninsula and northern and central Wisconsin. Top-producing counties were St. Louis, Koochiching,

and Itasca in Minnesota; Marinette, Oneida, and Price in Wisconsin; and Marquette Delta, and Iron in Michigan.

Pulpmills using Lake States timber in 1976 reported their pulpwood receipts by species groups and State and county of origin. Their cooperation is gratefully acknowledged. Thanks are also due the Michigan Department of Natural Resources for collecting the data from pulpmills in Michigan.

**ABSTRACT.**—Shelterwood-strip harvesting in a mature red pine stand provided favorable growing conditions for red pine seedlings established by planting nursery stock, by planting 10-week-old to 1-year-old tubelings, and by direct seeding. How long the shelterwood-strips can be left standing before they seriously affect seedling development remains to be determined.

OXFORD: 221.223:232:174.7(77) *Pinus resinosa*.

**KEY WORDS:** regeneration, planting, seeding, tubelings, visual quality.

A shelterwood-strip harvesting method was tested in 1970 in a 100-year-old red pine (*Pinus resinosa* Ait.) stand on the Cutfoot Experimental Forest in north-central Minnesota (Benzie and Zasada 1972). The method was designed to harvest mature timber, prepare the site for regeneration, provide environmental conditions to favor tree growth, and maintain the visual quality of the landscape.

The shelterwood-strip method resulted in a pattern of clearcut strips 50 feet wide and uncut shelterwood-strips 16 feet wide (fig. 1). Some strips were oriented north-south and some east-west; all led to a common landing. Full-tree harvesting was used—trees were felled into the cut strips and skidding was confined to the cut

strips. Limbing was done at the landing and the slash was piled and burned. Unmerchantable trees were cut, skidded, and burned with the slash to prepare the area for establishing a new red pine stand.

Figure 1. — Shelterwood-strip harvesting in red pine provided good environmental conditions for seedling establishment.

## ESTABLISHING REGENERATION

During good seed years the trees left in the shelter-wood-strips could supply up to a quarter of a million seeds per acre, but 1970 was a poor seed year and less than a thousand seeds per acre were produced. The 1-year-old conelets that would produce the 1971 seed crop were also poor. Therefore, 3-0 red pine seedlings, three age classes of red pine tubelings,<sup>1</sup> and untreated red pine seed were planted in the spring of 1971. At the time of planting the tubelings were 10 weeks, 16 weeks, and 1 year from date of seeding. The bare-root seedling stock was hand-planted without additional site preparation but tubeling and direct seeding planting sites were hand-scalped.

A row of nursery stock seedlings, tubelings, and a direct-seeded plot were established along each long edge and in the center of four north-south strips and four east-west strips. Each row had 10 nursery-grown seedlings, 10 tubeling seedlings from each of the 3 age classes, and 1 direct-seeded plot. This planting scheme resulted in a total of 240 nursery stock seedlings, 240 tubelings of each age class, and 24 seeded plots. Most of the seeded plots failed the first year and were reseeded the following spring.

### SURVIVAL AND HEIGHT OF REGENERATION

Mean survival on the north-south strips was higher than on the east-west strips after 6 years, but the differences were not significant (table 1). Conversely,

<sup>1</sup>Seedlings were grown in 9/16-inch diameter, 3-inch long plastic tubes (Ontario tubes).

Table 1. — Mean survival and height of red pine after 6 years by regeneration method and strip orientation

| Regeneration method         | North-south strips  |                | East-west strips    |                |
|-----------------------------|---------------------|----------------|---------------------|----------------|
|                             | Survival<br>percent | Height<br>feet | Survival<br>percent | Height<br>feet |
| 3-0 seedlings               | 61                  | 2.1            | 54                  | 2.3            |
| 1-year tubelings            | 78                  | 1.1            | 75                  | 1.4            |
| 16-week tubelings           | 72                  | 0.8            | 62                  | 1.1            |
| 10-week tubelings           | 47                  | 0.6            | 35                  | 0.8            |
| Direct seeding <sup>1</sup> | 3                   | 0.5            | 2                   | 0.5            |

<sup>1</sup>Direct seeding survival is tree percent (seedlings per 100 live seeds sown). Seven plots in the north-south strip and eleven plots in the east-west strips had tree percents less than 3 the first year and were reseeded the spring of the second year.

height growth was slightly greater on the east-west strips than on the north-south strips but again the differences were not significant.

Differences in survival and height by locations within the strips varied but generally survival was lower and height greater on portions of the strips that received longest exposure to midday sun. Survival was generally higher on the west edges of north-south strips and on the south edges of east-west strips. Height growth was generally greater on the north edge of east-west strips and on the east edge of north-south strips (table 2). The center plots had good height growth for both east-west and north-south strips.

Highest survival was obtained with 1-year-old tubelings. It was significantly higher than survival of the 3-0 nursery seedlings but not significantly higher than that of the 16-week-old tubelings. The survival of the 10-week-old tubelings was significantly lower than any of the other regeneration methods except direct seeding. The differences in survival between tubeling age classes are similar to those previously found after three growing seasons (Alm 1974). The recommended 16-week minimum cultural period for red pine tubelings is still valid after six growing seasons.

Direct seeding tree percent (number of surviving seedlings-per 100 viable seeds sown) was lower than the expected 5 to 10 percent.<sup>2</sup> So, under these conditions about 39,000 seeds (approximately 3/4 pound) would be required to establish 1,000 6-year-old seedlings per acre.

The majority (62 to 68 percent) of the trees die during the first winter and the first two growing seasons.

<sup>1</sup>East and west edges are on north-south strips, north and south edges are on east-west strips and the center plots include both strip directions.

<sup>2</sup>Direct seeding survival is tree percent (seedlings per 100 viable seeds sown).

<sup>3</sup>Means followed by the same letter do not differ significantly at the 0.01 level.

(1971-72). The major cause of death was smothering by leaves and other vegetation. Also, many seedlings were killed as a result of heavy deer activity in the cut strips.

Differences in height between regeneration methods were significant. As expected, the 3-0 seedlings were taller than all others. The next largest seedlings were the 1-year-old tubelings followed closely by those 16 weeks old. The 10-week-old tubelings and the direct-seeded seedlings were the smallest.

Red pine seedling establishment and early growth after harvesting by the shelterwood-strip method indicates generally favorable growing conditions within both north-south and east-west strips for all regeneration methods tested. Therefore use of the shelterwood-strip method need not be limited to a particular orientation of the strips. How long the shelterwood-strips can be left

before they seriously affect seedling development remains to be determined.

ROOT-CROWN RELATIONS OF YOUNG SUGAR MAPLE  
AND YELLOW BIRCHCarl H. Tubbs, *Principal Plant Physiologist*  
*Marquette, Michigan*

**ABSTRACT.**—Young forest-grown sugar maple and yellow birch (1 to 6 inches d.b.h.) crowns were mapped and roots excavated. Crown dimensions were compared. Sugar maple roots usually terminated within a few feet of the crown perimeter. Yellow birch roots frequently terminated well outside crown perimeters and roots of birch were more irregularly distributed than those of maple.

OXFORD: 181.62:181.36.

**KEY WORDS:** sugar maple, yellow birch, root distribution, crown dimension.

The trend toward more intensive culture of northern hardwoods has made it desirable to know more about root distribution of individual trees. Knowledge of root distribution can be used both in fertilizer application and in thinning. Also crown perimeter frequently is used to gauge thinning intensity and area of fertilizer application. This investigation sought to find a relation between crown perimeter and root extent and to also describe horizontal root distribution.

## METHODS

During the summer of 1975, the roots of 18 randomly chosen sugar maple and 18 yellow birch, ranging from 0.85 to 5.97 inches d.b.h. were excavated from a fully stocked stand that originated from a clear-cut in 1963. Soils were sandy loam podsols with a cemented layer at about 2 feet. Following the general method of Hannah (1972) all large lateral roots were excavated for their full length and diagrammed; crown perimeters were

measured and diagrammed on the same map. Root length was considered to be the straight line distance from the end of the root to the tree stem. Average root length was calculated from the four longest roots. The average crown radius was calculated using the radii at cardinal points. Trees were cut and total heights measured.

## RESULTS

## Root-crown-stem Size Relations

Most tree characteristics were closely related (table 1). Diameter breast height was well related to total height, average crown radius, and average root length. In turn, these characteristics are well related to each other. Crown radius was only slightly better related to the logarithm of d.b.h. than to d.b.h.; average yellow birch root length was better related to the logarithm of crown width than with actual data.

Small increases in stem diameter of both species were associated with disproportionately greater root lengths (fig. 1) in the smallest size classes; also small changes in crown radius of yellow birch were related to disproportionately large changes in root lengths (fig. 2). Average sugar maple root lengths and average crown radius were surprisingly close to a one-to-one ratio regardless of tree size. Average root lengths tend to exceed average crown widths in the smallest size classes (0.5 to 1.5 d.b.h.). Trees larger than 1.5 d.b.h. tended to have roots less than the average crown width. In general, the longest sugar maple roots were a few feet outside the perimeter.

Figure 1. — Average root length vs. diameter breast height for yellow birch and sugar maple.

Figure 2. — Yellow birch and sugar maple average root lengths vs. crown radius.

For example, the data shows that the longest roots of trees with a 2.5- to 3-foot crown radius were about 4 feet in length.

The ratio of root length to crown radius in yellow birch was generally less than 1:1 in the smallest size classes (up to 2 inches d.b.h.), but about 1:1 in the larger size classes.

## Root Distribution

Crown maps were divided into segments each equaling an 8th of a circle whose center was the tree stem. Boundaries of the segments were compass directions (to NE, NE to E, etc.). The number of segments in which roots fell were counted to provide an estimate of root distribution. Most yellow birch had short roots in all segments, but no tree had long roots (2 feet or longer) in all segments. Nine trees had roots in only 50 percent of the segments. There seemed to be no relation between root distribution and other tree characteristics.

Twelve of the 15 birch had roots extending beyond the actual crown perimeter. Of these, three trees had examined roots terminating beyond the crown and nine trees had roots terminating both within and beyond the crown.

Fifteen of the 16 maple had one or more roots extending beyond the actual crown perimeter. In many cases these roots did not extend more than 2 or 3 feet beyond the crown (in contrast to the birch whose roots occasionally grew 8 or 10 feet beyond). Seven maple trees 1 inch in d.b.h. had 50 percent or fewer of the segments penetrated by roots. The larger trees had better distributed root systems.

The vertical distribution of roots was not measured but variations from the typical were noted. Several birch and maple had sinker roots which grew straight down for some distance. One maple originated from a root sucker.

The actual distribution of the root mass in relation to the crown mass appeared to be much more variable in birch than in maple, as the previous data suggest. Maple crowns seemed to be more regular and roots were fairly evenly distributed (fig. 3). In contrast, birch crowns seemed quite irregular in shape and roots frequently were mostly on one side or other of the tree (fig. 4). Inspection of the maps of both species suggested that if the crown mass was off center from the stem, then the roots tended to fill in that part of the circle not occupied by the crown. This tendency is accentuated in leaning trees. The roots of leaning trees of both species always grew away from the direction of lean (and crown mass) as if to offset the imbalance created by the stem and crown (fig. 5).

Figure 4. — Yellow birch (5.3 inches d.b.h.) with irregular crown and root distribution.

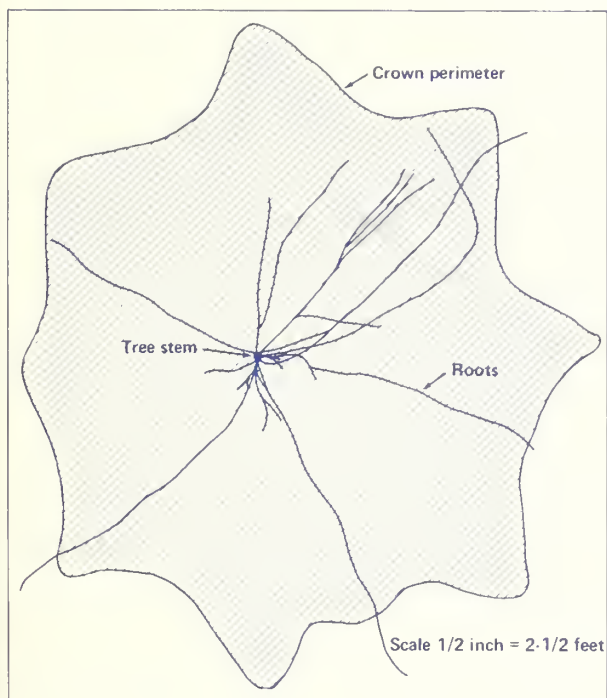

Figure 3. — Sugar maple (4.3 inches d.b.h.) with regular crown shape and well-distributed root system.

Figure 5. — Yellow birch (1.4 inches d.b.h.) leaning toward west illustrating direction of root mass.

## DISCUSSION AND SUMMARY

Because these trees were growing in an unthinned stand and were chosen more or less randomly on the basis of diameter, most were probably suppressed to some degree. Generally, this reduction in photo-synthetic capability would result in relatively poor root growth; more open grown trees might not show the relations noted in this study. This possibility seems greatest with yellow birch; the smaller and more likely to be suppressed trees had roots which ended close to the crown perimeter, while trees more than 2 inches d.b.h. grew roots which on the average ended well beyond the crown perimeter.

Sugar maple roots in the seedling stage, on the other hand, do not respond to reduction in light (Logan 1965) and appeared to be less suppressed in this study than yellow birch. Maple roots seemed sparse under the smallest trees and this may be internally regulated or the result of some suppression.

In contrast to red pines (Day 1941, Stiehl 1970) whose roots are so widespread that individual tree thinning has little effect, forest grown yellow birch and sugar maple have fairly regular root distributions. Distribution is irregular enough however, that it is probably a significant cause of variation between trees in thinning studies, and warrants some caution in thinning and fertilization. Fertilizing done under the crown of a leaning tree may miss the roots entirely (fig. 5) and carefully weighed and evenly distributed fertilizer may be only partially effective because of irregular root distribution.

Measurements were not made of the influence of surrounding trees on root distribution. It seems note-

worthy, however, that irregularities in crowns presumably caused by competitors were not necessarily copied by roots.

In summary, the average lengths of the main roots of yellow birch was greater than average crown length, especially in the smaller trees. The horizontal distribution of birch roots in relation to crowns was irregular and crowns were often irregularly shaped. Longest roots frequently were well outside crown perimeters.

Average sugar maple root area coincided closely to crown areas and longest roots frequently were within a few feet of the crown perimeter. The horizontal distribution of maple roots was fairly regular as were crowns.

Roots of both species were distributed away from the direction of lean of the tree.

ABSTRACT.--Biomass prediction equations were developed for 23 northeastern Minnesota shrub species. The allometric function was used to predict leaf, current annual woody twig, stem, and total woody biomass (dry grams), using stem diameter class estimated to the nearest 0.25 cm class at 15 cm above ground level as the independent variable.

OXFORD: 182.46:182.5(776). KEY WORDS: wild-life habitat, nonlinear regression analysis, allometric relations, dry weight, browse estimation.

A recent study (unpublished) to quantitatively describe a series of pine plantations in northeastern Minnesota as white-tailed deer and snowshoe hare habitat placed special emphasis on woody plants as potential browse. The descriptive information included shrub density and basal area. To estimate the browse represented by these data, equations were needed to determine the biomass of leaf and current annual woody-twig growth for each species. Reported here are the data collected and the resulting regression equations developed to produce the needed estimates. These equations should be useful to land managers, game managers, and other researchers who need to estimate biomass values for these species within the northern Lake States region.

For each of the major shrub species found in the plantations, stems spanning the size range were collected during the last half of

August 1976. In the plantation study, shrub diameters had been determined to the nearest 0.25 cm at 15 cm above ground level. In sampling for the biomass estimation equations, we attempted to collect individuals from the lowest, highest, and middle size class for each species. Thus, if a species occurred in the study in size classes 1 (0 to 0.25 cm) through 7 (1.50 to 1.75 cm), we selected a minimum of three typical stems within each of three size classes spanning that range: for example, size class 1, 4 (0.75 to 1.00 cm), and 7. For shrubs with small diameters, such as *Rosa blanda*, we selected only stems within the lowest three size classes.

The stems were selected in the field, clipped at ground level, and taken to the laboratory where the leaves and current annual woody-twig growth were each separated from the remainder of the woody stem. Each component of each stem was bagged separately and dried at 70 C to constant weight. Each component was weighed to the nearest 0.01 gram immediately after removal from the oven.

Because of dry weather during the summer of 1976, some shrub stems had lost a portion of their leaves by late August. In those cases no leaf data were collected and the number of leaf biomass observations used in the leaf biomass regressions was reduced.

The independent variable, stem diameter size class; and each dependent variable-leaf,

current annual woody-twig, stem, and total woody biomass were summarized for each species (table 1).

The numerical value used for stem diameter was the upper end of the diameter class range. Stems 0.50 to 0.75 cm diameter, for example, were considered to be 0.75 cm diameter in the data summary.

In earlier work estimating biomass of

five shrub species from northeastern Minnesota, we found that shrub biomass data conformed to the allometric function as well as or better than they did to alternative functional relations (Ohmann, Grigal, and Brander 1976)<sup>1</sup>.

<sup>1</sup>All the woody growth was determined to be current annual. Stem and total woody biomass regressions were identical to current twig.

In this study, then, the data for each species-variable combination were subjected to an iterative nonlinear, least squares regression analysis using the allometric relation

$$Y = aX^b \quad (1)$$

where Y is the biomass in grams dry weight of the dependent variable and X is the shrub diameter in cm at 15 cm above ground. The

regressions were tested for significance using a standard F-test.

The resultant equation elements are presented in table 2.

Species from northeastern Minnesota

ABSTRACT.--As part of a study describing vegetation biomass dynamics following wildfire in standing virgin forest communities, mean dry weight per individual for immature and mature tree, shrub, and herbaceous species for the 1971 through 1975 growing seasons in northeastern Minnesota are presented.

OXFORD: 182.41:182.46:182.47:181.5(776).

KEYWORDS: standing crop, plant productivity, wildfire, virgin forest, vegetation dynamics.

A recent search of the literature revealed that, except for mature tree species, there is a striking lack of published data on biomass of individual plants (Ohmann and Grigal, in preparation). This note provides mean biomass for individuals of some immature and mature tree, shrub, and herbaceous species.<sup>1</sup> The data were collected during a study of the post-fire vegetation biomass changes following the Little Sioux Wildfire of 1971 in northeastern Minnesota.

The aboveground crop of vegetation was harvested during August of each of the first 5 years following the fire. All vegetation in 10 randomly located plots (each 0.605 m<sup>2</sup>) within each of seven post-fire plant communities was clipped at ground level. Thus, a to-

tal of 70 plots or 42 m<sup>2</sup> was sampled each year. Each plot was marked following clipping to ensure that it would not be clipped again in succeeding years.

All vegetation from the clipped plots was sorted by species in the laboratory. The number of individuals of each species on a plot was recorded, and the samples for a plot were bagged, dried at 70 C to constant weight, and weighed by species to the nearest 0.01 gram.

The total weight of each species from all seven communities was divided by the total number of individuals of that species in the sample to derive the mean dry weights (table 1).

Year-to-year variability in mean individual dry weights can be ascribed to growth (particularly of the woody species), the presence of many smaller individuals resulting from germination of the previous year's seed crop (*Aster macrophyllus*, for example), disease infestation (*Venturia* shoot blight on *Populus grandidentata* in 1973, for example), variation in annual precipitation available for growth (the precipitation from August 1972 through July 1973 was lower than that for the other growing seasons and lower than the 30-year average for the area), sampling variation, and experimental error.

<sup>1</sup>We thank Ms. Devvie Cercine for help in sample collection and processing.

Table 1.--Average individual dry weights and numbers of individuals sampled at the end of the 1971 through 1975 growing seasons on the Little Sioux Wildfire Area of northeastern Minnesota

In our analysis of the revegetation dynamics of the seven burned communities (Ohmann and Grigal, in preparation), we found that the low shrub and herb strata had stabilized in terms of dry weight per unit area by 1974. On that basis, we assume that most low shrub

and herb weights presented for 1974 and 1975 represent weights that can be found in mature forest communities. The trees and tall shrubs were still increasing in biomass in 1975, and so the values presented can generally be considered to represent immature individuals.

## NUTRITION AND *IN VITRO* DIGESTIBILITY OF TALL FESCUE FOR WHITE-TAILED DEER, MAY THROUGH NOVEMBER

G. E. Probasco, *Associate Research Wildlife Biologist*  
*North Central Forest Experiment Station*  
*Columbia, Missouri*

and A. J. Bjugstad, *Supervisory Range Scientist*  
*Rocky Mountain Forest and Range Experiment Station*  
*Rapid City, South Dakota*

**ABSTRACT.**—Describes a study of the nutritive quality and digestibility of fertilized and unfertilized tall fescue in spring, summer, and fall. The grass may be most valuable as food in early spring and late fall, and on unfertilized sites.

**OXFORD:** 268.3:149.6 **CERVID.** **KEY WORDS:** range, wildlife, food habits, wild ruminants, *Odocoileus virginianus*, forage quality.

Conversion of low-quality hardwood forest to tall fescue (*Festuca arundinacea* Schreb.) grassland (fig. 1) in the Ozarks is producing different food and cover conditions for the resident white-tailed deer (*Odocoileus virginianus*) population. Resource managers are concerned about the impacts of this conversion on wildlife populations and question the contribution of this process to the life requirements of deer. Deer have been known to utilize tall fescue, a cool season perennial grass, because animals collected in converted areas during the November hunting season sometimes have fescue in their rumens. Also, Short and Segelquist (1975) have found Elbon rye (*Secale cereale* L.), a cool season annual grass, to be heavily used by deer when available.

The present study was designed to examine the nutritive quality and digestibility of fertilized and unfertilized tall fescue with respect to use in late spring, summer, and fall, when it is most abundant.

Figure 1. — A typical converted area. Number board is 24 inches tall.

## METHODS

Forage samples were collected from fertilized and unfertilized fescue stands during May, July, September, and November. Collection sites were upper north- and south-facing slopes located in the White River basin of southern Missouri. Forage samples were clipped to a 2-inch stubble, oven-dried at 70C using a 2-mm screen to provide samples for chemical analysis and *in vitro* digestibility trials. Percents of crude protein, calcium, phosphorus, and acid detergent fiber were determined by the Agricultural Experiment Station Chemical Laboratories, University of Missouri, Columbia. *In vitro* digestion trials were performed by the ARS-University of Missouri facilities using the two-stage technique of Tilley and Terry (1963).

Deer rumen fluid samples were collected through the assistance of the Missouri Department of Conservation research personnel, Columbia, Missouri. Captive animals were maintained on a diet similar to that described by Snider and Asplund (1974). Rumen fluid samples were transported to the laboratory in sealed, insulated containers; inoculation of forage samples began within 2 hours after collection.

The experimental design was a three-factor factorial with two levels of fertilizer (0 and 48 pounds/acre, N, P, K), two aspects (north and south) with two plots on each aspect, and four harvest dates. All data were subjected to standard analysis of variance procedures. Statements of significance are based on this analysis; significant effects were further subjected to Duncan's New Multiple Range Test at the 5 percent level.

## RESULTS AND DISCUSSION

Fescue in May had a crude protein content of 16.2 percent (table 1)—a value higher than the 13 percent Murphy and Coates (1966) determined as adequate for reproduction and close to the 16.8 percent protein figure which McEwen *et al.* (1957) cited as yielding good growth and antler production. Protein in fescue declined in July to 9.1 percent and remained at about that level in September (9.3) and November (9.5). These values are comparable to the 9 to 10 percent ratio used by McEwen *et al.* (1957) to obtain some growth but retarded antler development. Protein level in fescue during the summer is below the 15.0 percent average found for the preferred native summer foods of Missouri deer (Torgerson and Pfander 1971). Protein did not vary significantly with respect to fertilizer treatment or aspect.

Table 1. — Mean nutritive values and dry matter digestibility of tall fescue forage by harvest date

| Harvest date | Protein | Ca   | P    | Ratio of | ADF <sup>1</sup> | DMD <sup>2</sup> |
|--------------|---------|------|------|----------|------------------|------------------|
|              | Percent |      |      | Ca/P     | Percent          |                  |
| May          | 16.2    | 0.31 | 0.29 | 1.13     | 30.7             | 61.3             |
| July         | 9.1     | .43  | .21  | 2.31     | 35.2             | 51.4             |
| September    | 9.3     | .36  | .26  | 1.53     | 37.5             | 50.9             |
| November     | 9.5     | .29  | .25  | 1.28     | 31.0             | 55.9             |

<sup>1</sup>ADF—acid detergent fiber.

<sup>2</sup>DMD—dry matter digestibility.

Calcium and phosphorus levels (table 1) are considerably lower than the 0.64 and 0.56 percent respectively maintained by McEwen *et al.* (1957) in an ideally complete ration. Our values are closer to what they considered to be the winter minimum of 0.30 percent for these minerals. The calcium levels varied from 0.31 percent in May to 0.43 percent in July, 0.36 percent in September, and 0.29 percent in November. This was considerably below the 1.95 percent average found for the preferred summer foods of Missouri deer (Torgerson and Pfander 1971). Fescue phosphorus levels varied little from those of the preferred summer deer foods.

When fertilizer was applied, calcium content of fescue increased on the north slopes but decreased on the south slopes.

Phosphorus levels attained the minimum of 0.30 percent recommended by McEwen *et al.* (1957) only on the fertilized plots. The average phosphorus content over the sampling period was 0.29 percent in May, 0.21 percent in July, 0.26 percent in September, and 0.25 percent in November.

The Ca/P ratio exhibited a significant response to both date of harvest and fertilizer treatment. All values of the ratio remained close to or within the acceptable limits (2:1 to 1:2) for ruminant animals (Maynard and Loosli 1962). Ca/P ratio varied over the sample period from 1.13 in May to 2.31 in July, 1.53 in September, and 1.28 by November. Samples from fertilized plots had a Ca/P ratio of 1.19, while samples from unfertilized plots had a Ca/P ratio of 1.93.

Fiber content (table 1) did not change appreciably over the sampling period: acid-detergent fiber values were 30.7 percent in May, 35.2 percent and 37.5 percent for the mature forage of July and September respectively, and 31.0 percent for the fall growth accumulated to November. There were no significant differences due to fertilizer or aspect; however, there was an interaction (fig. 2) between harvest date and fertilizer treatment because samples from fertilized plots contained lower amounts of fiber initially. The fiber content increased

Figure 2. — Graph of the interaction between fertilizer treatments for acid-detergent fiber.

after the first sample date thus unfertilized samples contained less fiber for the remainder of the sampling period. This effect may be a result of increased growth due to fertilizer application.

Dry matter digestibility coefficients (table 1) varied as the fescue developed throughout the season, dropping from 61.3 percent in May to 51.4 percent in July, to 50.9 percent in September, and rising up to 55.9 percent for November. Fertilizer treatment significantly influenced dry matter digestibility. Samples from fertilized plots had a coefficient of 53.2 and those from unfertilized plots 56.6. This difference seems due to the ranker growth and increased fiber production which may have resulted from fertilization.

Tall fescue is not an important spring or summer deer food in Missouri according to Korschgen *et al.* (1976). They found fescue in only 34 of 304 Ozark deer stomachs during spring and summer and it contributed only 0.2 percent of the total food volume. The widespread availability of fescue and low consumption indicates low palatability for deer from April through September. But when eaten, fescue is above average in digestibility. Digestibility coefficients in this study were higher than the average of 47.9 percent found for preferred summer foods of Missouri deer (Snider and Asplund 1974). Fescue does have less crude protein and calcium than preferred summer deer foods. Tall fescue as a food source for deer may be most valuable in early spring, late fall, or both, and on unfertilized areas,

because fescue on these areas was higher in dry matter digestibility.

## SUMMARY

1. Harvest date and fertilizer treatment have more effect on nutritive value and digestibility of fescue than exposure.

2. Protein, acid-detergent fiber, and dry matter digestibility were at the most desirable levels early and late in the sampling period. Calcium and phosphorus were very low throughout the study. The calcium-phosphorus ratio did not appear to be limiting, however.

3. Acid-detergent fiber and dry matter digestibility values for unfertilized samples were superior to the values for fertilized samples.

## TWO YEARS NECESSARY FOR SUCCESSFUL NATURAL SEEDING IN NONBRUSHY BLACK SPRUCE BOGS

Elon S. Verry, *Forest Hydrologist*  
and Arthur E. Elling, *Physical Science Technician*  
Grand Rapids, Minnesota

ABSTRACT. — Natural seeding in a strip-cut black spruce bog was adequate, averaging 1,800 stems per acre and 80 percent milacre stocking. Natural seeding in a completely cut bog was inadequate, averaging 630 stems per acre and 40 percent milacre stocking. Slash was removed to expose sphagnum seedbeds in both cases. Progressive cutting every other year is recommended.

the entire stand is harvested and no standing seed source remains. We had the opportunity to measure natural seeding success on a 20-acre black spruce bog on the Marcell Experimental Forest in the Marcell Hills country 50 miles south of the Big Falls Experimental Forest.

KEY WORDS: *Picea mariana*, direct seeding, swamp conifers, conifer reproduction, peatlands, Minnesota.

Guidelines for black spruce (*Picea mariana* (Mill.) B.S.P.) regeneration are well established from studies on the Big Falls Experimental Forest in north-central Minnesota—an area of extensive peatlands on the bed of glacial Lake Agassiz (Johnston 1977). Clearcutting and slash removal is all that is required for black spruce to reproduce rapidly and abundantly if (1) the peatland is not brushy, (2) *Sphagnum* spp. moss seedbeds are well distributed, and (3) natural seeding is ample. However, the success of these conditions has not been documented for small, isolated, lake-filled peatlands in glacial moraine country, nor has the success of natural seeding been measured where

### PROCEDURE

The study area was a nonbrushy black spruce bog about 2,000 feet long and 500 feet wide oriented approximately north-south along the major axis. The bog had two stands with the following characteristics in 1968:

| Stand characteristic          | Older stand | Younger stand |
|-------------------------------|-------------|---------------|
| Age (years)                   | 73          | 62            |
| Site Index (feet at 50 years) | 40          | 31            |
| Basal area (square feet/acre) |             |               |
| (Stems > 0.5 inches d.b.h.)   | 157         | 122           |
| Volume (cords/acre)           | 20          | 14            |

Apparently the southern half of the bog burned and black spruce seedlings were re-established in 1906. Both stands had practically a continuous ground cover of lush sphagnum moss with clumps of Labrador-tea, leather-leaf, and fine-leaved sedges scattered throughout.

Both black spruce stands were partially harvested in February 1969 by clearcutting 100-foot-wide, east-west strips and leaving 150-foot-wide uncut strips. All slash was put into a few piles, thus exposing practically all of the ground in the clearcut strips. Three growing seasons later (August 1971) seedlings were counted on 25 ¼-milacre plots in the clearcut strips of each stand and advance reproduction was similarly counted in the uncut strips.

The remaining 150-foot-wide strips were harvested in January, 1974, and all slash was progressively piled and burned. In November, 1975 (seven growing seasons after harvesting), reproduction in the 100-foot-wide strips was resampled on 38 milacre plots in each stand. In November, 1976 (three growing seasons after harvesting), reproduction in the 150-foot-wide strips was counted on 51 milacre and 51 ¼-milacre plots in each stand. All regeneration data were converted to number of stems per acre and percent milacre stocking. Between densities of 500 and 2,000 stems per acre, ¼-milacre stocking times 2.63 equals milacre stocking in each stand.

## RESULTS AND DISCUSSION

The 100-foot-wide strips regenerated successfully. Three growing seasons after cutting there were about 1,800 seedlings per acre in each stand (table 1). Although these densities are only 8 to 15 percent of those reported for similar conditions in black spruce stands on the Big Falls Experimental Forest (Johnston 1975), milacre stocking is about 80 percent for each stand on the Marcell Experimental Forest. Therefore, we conclude that the new black spruce forest is adequately stocked. Seven growing seasons after cutting (5 years with a standing seed source), seedling numbers increased to about 2,300 per acre, and milacre stocking remained about 80 percent.

One reason for the lower densities on the Marcell study area may be the lush sphagnum growth which is typical on small, nonbrushy, acid bogs. Measurements for 3 years showed that sphagnum moss grows about 4 inches each spring and 2 inches each fall during periods of cool temperatures and high humidities. Therefore, some young seedlings may have been smothered by the moss and those that survive typically produce adventitious roots in the new moss growth (fig. 1).

The 150-foot-wide strips had a nonbrushy, well-distributed sphagnum seedbed, but the only seed source was seed dispersed before or during cutting. Advance reproduction in the younger stand survived the logging, but the larger advance reproduction in the older stand was either cut or crushed. Both stands had about 225 stems of advance reproduction after harvesting (table 2).

About 400 new seedlings per acre were present after cutting with 30 percent milacre stocking in each stand. When new seedlings and advance reproduction are combined, they total about 625 stems per acre and 40 percent milacre stocking for each stand (table 2). Sixty percent milacre stocking is considered necessary for an adequately stocked stand (Johnston 1977); therefore, harvesting the entire seed source and relying on previously dispersed seed will not result in adequate, rapid regeneration. Black spruce seed remains viable for only about 12 months on upland

Table 1.—Black spruce reproduction 3 and 7 growing seasons after strip cutting with slash removed on a nonbrushy, medium site with well-distributed Sphagnum moss

| Growing seasons after strip cutting | Stems per acre |               | Milacre stocking |               |
|-------------------------------------|----------------|---------------|------------------|---------------|
|                                     | Older stand    | Younger stand | Older stand      | Younger stand |
| 3                                   | 1,770          | 1,770         | 81               | 76            |
| <sup>1</sup> 7                      | 2,380          | 2,220         | 81               | 81            |

<sup>1</sup>Remaining 150-foot wide strips (seed source) were harvested after 5 years.

| New reproduction                   |                |               |                  |               |
| 3 years after cutting              | 450            | 360           | 30               | 30            |
| Total reproduction                 |                |               |                  |               |
| 3 years after cutting              | 680            | 580           | 40               | 42            |

or peatland seedbeds (Fraser 1976), thus seed storage in the moss cannot be relied on to increase milacre stocking in subsequent years.

Overall, our data show about 40 percent milacre stocking after one growing season, with only the previous fall's seed, and about 80 percent milacre stocking after three growing seasons with 2 years of standing seed source and the fall seed prior to harvesting. Interpolating, we might assume a 60 percent milacre stocking after two growing seasons with a continuous seed source. Since 60 percent milacre stocking is the lower limit of adequate stocking, we suggest that two years of seed (the fall before cutting and the fall after cutting) are required to secure the minimum stocking level in black spruce stands on small, nonbrushy bogs. To secure stocking levels greater than the minimum we suggest that three years of seed (the fall before cutting and two falls after cutting) are needed.

## MANAGEMENT IMPLICATIONS

Nonbrushy, black spruce bogs can be regenerated successfully if they have a well-distributed sphagnum seedbed and if slash is removed to expose it. Full-tree skidding, with slash burning at the landing, has been recommended as a practical method for achieving these conditions (Johnston 1975). Though much of the slash removal was done by hand in our study, it closely simulates a full-tree skidding operation. However, completely harvesting black spruce bogs of 5 to 50 acres during one season will not leave sufficient seed to regenerate the stand rapidly.

Areas larger than 50 acres should be progressively strip-cut no more frequently than every other year in order for the clearcut area to reach 80 percent milacre stocking. Although risky, it is possible that the cutting could be done every year if only the minimum stocking level (60 percent) is desired. Some wind mortality will occur along exposed edges of stands that are left but most trees can be salvaged every other year. Strip widths should not exceed natural seeding distance (about 400 feet). After the last cut, direct seeding may be necessary if a natural seed source is not available.

Bogs of 50 acres or less can also be progressively cut although only two cuts may be feasible. Entire bogs can be harvested with full-tree skidding to expose the seedbed and then be direct seeded. If slash removal and direct seeding are not done the regeneration will have less than full stocking (probably less than 40 percent), and it will take about 15 years for the new trees to begin to provide seed to fill in the nonstocked or understocked areas.

The choice will depend on management goals, the cost of direct seeding, and the presence of dwarf mistletoe. If dwarf mistletoe is abundant, slash should be broadcast and burned (Johnston 1977). Most small bogs can be seeded by hand with a cyclone seeder at the recommended seeding rate of ¼-pound per acre (Johnston 1977). Seed cost is about \$50 per pound, thus regeneration costs for seeding alone should be about \$15 per acre. Skidding and slash burning will add to costs. Usually natural seeding can be relied on if sale areas in nonbrushy black spruce peatlands are laid out skillfully, but some small areas will need direct seeding to provide full and rapid stocking.

# SOIL WATER DEPLETION AFTER FOUR YEARS OF FOREST REGROWTH IN SOUTHWESTERN WISCONSIN<sup>1</sup>

**Richard S. Sartz**, formerly Principal Hydrologist, now retired  
LaCrosse, Wisconsin  
and **M. Dean Knighton**, Associate Plant Ecologist  
Grand Rapids, Minnesota

**ABSTRACT.**—The effect of cutting on water depletion from a 150-cm soil mantle does not appear to have diminished by the 7th year after the trees were cut. Mean seasonal depletion was 41, 64, and 146 mm for all vegetation removed, woody vegetation only removed, and uncut treatments, respectively. After 4 years of regrowth, the original bare and clearcut treatments depleted only 21 and 35 percent as much water as the uncut forest.

**OXFORD:** 114.122:116.254(775). **KEY WORDS:** evapotranspiration, percolation, water storage.

### METHODS

The study site, a forested north slope on the Coulee Experimental Forest in southwestern Wisconsin, has been described previously (Sartz 1972a). Annual precipitation averages 800 mm, about two-thirds of which falls as rain during the growing season (May to mid-October). Soil water content is normally greatest in early spring, diminishing gradually over the growing season because of evapotranspiration and drainage. Rarely do summer rains recharge the soil mantle

<sup>1</sup>The research was conducted in cooperation with the State of Wisconsin Department of Natural Resources.

enough to deliver water to the ground water system.

The original study design included four treatments: (1) woody vegetation only removed ("clearcut"); (2) all vegetation removed ("bare") (in addition to cutting the trees, the herbaceous vegetation was killed or clipped for 3 years on a circular plot 2 m in diameter to minimize transpiration loss); (3) uncut; and (4) uncut forest with litter removed. However, after it was found that litter removal did not affect water depletion, the data for the two uncut treatments were combined.

Each treatment had four replicates in a paired-plot design for the secondary treatments (plots with woody vegetation removed vs. plots with all vegetation removed, and plots with litter removed vs. undisturbed plots). The paired plots were centered in 62- by 44-m blocks that were laid out along a 265-m stretch of slope. A block width of 44 m was considered to be the minimum needed to overcome border effects. Mean slope is 32 percent.

Originally one neutron meter access tube was installed in each plot, but after analysis of sampling variation in the first year's data (Sartz 1972a), a second tube was added. Each tube was

treated as an independent sample, resulting in 8 samples for each of the clearcut treatments and 16 for the uncut forest treatment after the first year. Details of the study site, installation of access tubes, and a description of the neutron meter and measuring procedure, are given in two previous papers (Sartz 1972a, 1972b).

Soil water content was logged with the neutron meter in early spring (about mid-May) and again in late summer. Readings were taken at 30-cm intervals beginning at a depth of 30 cm. Sampling depth differed among plots according to depth to the layer that could be penetrated by hand augering. This was assumed to be the lower limit of the soil mass affected by transpiring vegetation. All plots (tubes) could be sampled to 120 cm, and 4 bare, 4 clearcut, and 11 uncut plots to 150 cm or deeper. Depletion values are based on the modal depth of 150 cm.

Seasonal depletion was assumed to be the difference between early spring and late summer water contents during the 4-year period of regrowth reported here. Measurements were made at 2-year intervals.

## RESULTS AND DISCUSSION

Water content at the beginning of the growing season was similar for each of the 5 years (3 initially, plus 2 during the 4-year regrowth period) studied. Means for the 150-cm soil mantle ranged from 468 to 481 mm for the three conditions (table 1). This is about 30 percent by volume, and approximates field capacity. Considering the sampling errors involved (Sartz 1972a) it seems reasonable to assume that the soil mantle was fully charged on all plots each spring.

### Vegetation Changes

Herbaceous vegetation was suppressed on the bare plots but was allowed to grow on the clearcut plots during the initial 3 years of study. Ferns grew denser and blackberries (*Rubus* spp.), hazel (*Corylus americana* Marsh), and other weed

Table 1.—Water content of a 150-cm soil mantle at the beginning of the depletion period.

| Forest Condition | Before regrowth |      |      | After regrowth |      | Mean |
|------------------|-----------------|------|------|----------------|------|------|
|                  | 1969            | 1970 | 1971 | 1973           | 1975 |      |
| Bare             | 484             | 508  | 482  | 463            | 466  | 481  |
| Clearcut         | 466             | 490  | 460  | 467            | 461  | 469  |
| Uncut            | 471             | 472  | 460  | 481            | 455  | 468  |

species invaded many plots. The cut plots were covered with a dense tangle of blackberries, ferns, and tree sprouts by 1973 (5 years after cutting, and 2 years after vegetation was allowed to grow). Two years later, the area was an impenetrable jungle. Aspen sprouts were up to 3 m tall, and trails cut through the plots for the spring measurements were completely grown over by the end of the summer. Some of the bare plots that had been treated with the herbicide simazine 80W in 1969 still had sparse growth around the neutron meter access tubes, but most could not be distinguished from the tangle that surrounded them.

### Soil Water Depletion

Four years of regrowth appeared to have little effect on soil water depletion (table 2). Since the data showed no trend with time, means were computed from the five sets of measurements. The values, expressed as a percent of depletion by the uncut forest, were 26 and 42 for the bare and clearcut treatments, respectively. Mean seasonal water depletion by depth for a 7-year period was similar for cut and uncut plots as seen in the following tabulation:

| Depth (cm) | Bare | Clearcut (Percent) | Uncut |
|------------|------|--------------------|-------|
| 30         | 25   | 21                 | 25    |
| 60         | 21   | 18                 | 21    |
| 90         | 23   | 21                 | 21    |
| 120        | 18   | 23                 | 18    |
| 150        | 13   | 17                 | 15    |

Because depletion values reflect rainfall gains as well as evapotranspiration losses, one would expect the values to vary from year to year, even with an unchanging vegetation. Thus, in 1973, high July-August rainfall (280 mm compared with 100 to 140 mm the other years) tended to mask the losses from evapotranspiration. Differences in the length of the depletion period and in potential

Table 2.—Seasonal water depletion in a 150-cm soil mantle

| Forest condition | Before regrowth |         |        | After regrowth |        | Mean   |

|                  | 1969            | 1970    | 1971   | 1973           | 1975   |        |
| Bare             | 29(15)          | 77(41)  | 64(35) | 8(17)          | 25(21) | 41(26) |
| Clearcut         | 58(29)          | 120(64) | 85(47) | 15(33)         | 42(35) | 64(42) |
| Uncut            | 197             | 187     | 181    | 46             | 120    | 146    |

<sup>1</sup>Figures in parentheses are seasonal water depletion as a percent of depletion in uncut plots.

evapotranspiration would also affect the amount of depletion measured from one year to another. This is an inherent weakness in the depletion method of comparing water use by different vegetations.

Soil water depletion by cut and uncut forest in the Driftless Area of southwestern Wisconsin was studied by Sartz (1972b). Seasonal depletion attributed to evapotranspiration in a 150-cm soil mantle averaged 188 mm on uncut plots, 87 mm on clearcut plots, and 57 mm on plots without vegetation. Similar relations have been reported from other regions using streamflow as the measured parameter; however, the initial effect of forest cutting diminished rapidly with the regrowth of vegetation (Lull and Reinhart 1967). Four years after clearcutting, the initial gain in streamflow had diminished 53 percent on a West Virginia stream (Lull and Reinhart 1966) and 36 percent on a North Carolina stream (Kovner 1956). An exception to this was reported by Mader, MacConnell, and Bauder (1972) in Massachusetts when the vegetation removed was in the riparian zone. They showed that increases in soil water storage were maintained in spite of rapid regrowth of herbaceous vegetation.

The change in soil water depletion reported by Sartz (1972b) in the Driftless Area was the result of 3 consecutive years of maintaining the vegetation according to the prescribed treatments. Beginning with the fourth year after timber removal, vegetation was allowed to regrow to assess the effect of regrowth on water depletion. This paper reports the results from a 4-year period of regrowth.

In view of the rapid reduction in streamflow with forest regrowth found on Appalachian catchments (Lull and Reinhart 1967, Troendle 1970) it seems surprising that the soil water depletion differences between cut and uncut forest reported here persisted with no apparent diminution through a period of vigorous vegetation regrowth. Perhaps the difference between

their results and these is related to differences in the kind of regrowth. The dominant regrowth on these plots was largely herbaceous; and even though it appeared to provide a continuous green cover, its transpiring surface was obviously much smaller, and its root system much less developed than in the uncut forest. Regrowth on the Appalachian catchments probably included more tree sprouts, which, using the already developed root systems of the parent trees, would be able to extract more water from the soil.

# SURVIVAL AND EARLY GROWTH OF SELECTED TREES ON WASTE WATER APPLICATION SITES

John H. Cooley, *Principal Silviculturist*  
*East Lansing, Michigan*

**ABSTRACT.** — The response of six tree species and three *Populus* hybrids to irrigation with oxidation pond effluent were compared. When weeds were intensively controlled, a *P. deltoides* x *P. nigra* cross responded best, but when weeds were less intensively controlled, *P. canescens* x *P. tremuloides* responded best.

**OXFORD:** 232.43:(628.35). **KEY WORDS:** sewage effluent, growth, survival, irrigation, waste water, nutrient removal.

Land application of waste water has many advantages for small and medium sized communities, especially if construction and operating costs can be partially offset by growing crops on application sites. In the north-central United States, agricultural crops cannot be grown on many sites, because of the soil, terrain, and climate, but tree crops can be grown on most sites in the region. We conducted this study in the Lower Peninsula of Michigan, at Middleville and Harbor Springs, to evaluate the response of selected tree species and *Populus* hybrids to irrigation with oxidation pond effluent.

## MIDDLEVILLE

The first test site was at Middleville in Barry County, on a gravelly morainal soil of the Boyer series, a typic hapludalf. Most of this site was nearly flat and had a plow layer of fine loamy sand. There were some slopes of more than 5 percent where surface soil had eroded exposing a gravelly sand, and part of the area was filled and covered with approximately 30 cm (1 foot) of very stony loamy sand.

Approximately 30mm (1.18 inches) and 70 mm (2.75 inches) of effluent was applied in 8 to 10 hours each week during the growing season. Nitrogen loading increased in 1975 and 1976 because concentration in the effluent increased sharply (table 1).

A split-plot design was used to test the effect of irrigation on the survival and growth of the trees. Application rate was the main plot treatment and subplots were planted to the species and hybrids selected for testing. In one set of nine plots each application rate and a control were replicated three times. In 1972, seedlings of *Populus*

*canescens* x *P. grandidentata* hybrid, Japanese larch (*Larix leptolepis*), European larch (*Larix decidua*), and tulip poplar (*Liriodendron tulipifera*) were planted in 25-tree subplots and northern red oak (*Quercus rubra*) seedlings were planted in a 28-tree subplot on each of the nine plots. Each application rate and the control were replicated twice in another set of six plots. Seedlings of green ash (*Fraxinus pennsylvanica*) and white-cedar (*Thuja occidentalis*) were each planted in two 25-tree subplots and 8-inch hardwood cuttings of 'Raverdeaux' poplar (a *P. deltoides* x *P. nigra* hybrid) were planted in one 28-tree subplot on each of these six plots. In 1973, a sixth 25-tree subplot in each plot of the nine-plot set was planted with hardwood cuttings of 'Raverdeaux' poplar taken from the 1972 planting. Spacing in all plots was approximately 1.2 m by 1.2 m (4 feet by 4 feet).

Plots were rototilled thoroughly before planting. Plots were not kept weed free but weed growth was greatly reduced by tilling, mowing, and using herbicides during the first 2 years.

## Survival

The species and hybrids differed in their ability to survive without irrigation. Nearly all of the nonirrigated 'Raverdeaux' poplars planted in 1972 and 88 percent of the green ash were alive after five growing seasons (table 2) whereas only 65 percent of the *P. canescens* x *P. grandidentata* hybrid and 53 percent of the northern red oak survived without irrigation. Less than 50 percent of the other selections lived.

Irrigation increased survival of tulip poplar but had no significant effect on survival of any of the other selections planted in 1972. Apparently rainfall was adequate to prevent critical moisture stress during establishment. The 'Raverdeaux' poplar planted in 1973 survived significantly better with irrigation than it did without because there was not enough rain in 1973 to prevent critical moisture deficits on nonirrigated plots. Irrigation with 70 mm/week did not increase survival significantly more than irrigation with 30 mm/week.

Many of the *P. canescens* x *P. grandidentata* that died after the first year appeared to be girdled by a canker that has not yet been positively identified. Because cankers were only associated with mortality that occurred during the first 2 years and inoculation did not produce cankers in

<sup>1</sup>Dry weights are estimates based on average height using equations derived by weighing a random sample of 24 to 58 trees from each selection.

<sup>2</sup>Different letters following means for the same selection denote significant differences ( $P \leq 0.10$ ).

vigorous 4-year-old trees, it appears that the canker only kills trees that are under stress during establishment.

Much of the mortality that occurred on irrigated plots was related to the grass and weeds that developed despite control efforts. Many of the Japanese larch that died during the first 3 years had sustained heavy feeding by June beetle larvae (*Phyllophaga* sp.). The heaviest feeding was on irrigated plots that had the most herbaceous ground cover. Mice girdled many of the white-cedar on irrigated plots after weed control was stopped.

## Growth

After five growing seasons, average height of nonirrigated trees ranged from about 1/2 m for white-cedar to nearly 4 m for the 'Raverdeaux' poplar (table 2). The average dry weight of whole trees ranged from 0.135 kg for European larch to 2.767 kg for 'Raverdeaux' poplar. The average height of all irrigated trees exceeded the average of those that were not irrigated, but the differences were only significant ( $P < 0.10$ ) for 'Raverdeaux' poplar, green ash, and white-cedar. Irrigation increased the average height of these trees by 64, 46, and 67 percent, respectively, and their average dry weight by 275, 177, and 40 percent. Irrigation with 70 mm/week did not increase growth significantly more than irrigation with 30 mm/week.

Irrigation increased average height of the 'Raverdeaux' poplar planted in 1973 by 169 percent and its dry weight by nearly 1,200 percent. Again there was no significant difference in the effects of the two irrigation rates. The difference in response of the two 'Raverdeaux' plantings could be a reflection of differences in age or differences in weather during the year of establishment. However, it seems likely that removal of shoots from the first planting when it was 1 year old to provide cuttings for the second planting partially offset its response to irrigation.

## HARBOR SPRINGS

The second test planting was on the application site for the Harbor Springs Area Sewage Disposal Authority near Petoskey in Emmet County. Soils were sands and loamy sands of the Kalkaska and Blue Lake Series, typic and alfic haplorthods,

respectively, underlain at 45 to 120 cm (1.5 to 4 feet) with gravel. This site had a well established ground cover of grasses and forbes.

*Populus* hybrids were selected for a larger scale trial on this site because of their superior performance in the initial trial at Middleville. Nonrooted cuttings of 'Raverdeaux' poplar were planted as at Middleville, and some rooted cuttings were planted as well. *Populus canadensis* x *P. tremuloides* was planted instead of *P. canadensis* x *P. grandidentata* because it was thought to be more suited to the climate and soils at Harbor Springs. Instead of tilling to prepare for planting, a 2-foot strip was sprayed with a herbicide. Weed control after planting was much less intensive than it was at Middleville.

Each of the two hybrids was planted in two plots 36.6 m by 61.0 m (120 feet by 200 feet) and two that were 21.3 m by 61.0 m (70 feet by 200 feet). Rooted cuttings of 'Raverdeaux' poplar were planted in one of the smaller plots. Trees were spaced approximately 2.7 m by 2.7 m (9 feet by 9 feet). One-hundred and twelve 'Raverdeaux' poplars and 47 *P. canadensis* x *P. tremuloides* seedlings were planted outside the irrigated area.

One half of each plot was irrigated at the rate of 3.9 mm (0.15 inch) per hour and the other half at the rate of 8.6 mm (0.34 inch) per hour (table 3).

## Survival

After three growing seasons, 72 percent of the *P. canadensis* x *P. tremuloides* seedlings on irrigated plots were still alive (table 4). Survival of non-irrigated seedlings was 89 percent.

Table 3. — Annual effluent, nitrogen, and phosphorous loadings for two effluent application rates at Harbor Springs, Michigan

| Year        | 3.9 mm/hour    |            |       |
|-------------|----------------|------------|-------|
|             | Effluent<br>mm | N<br>kg/ha | P     |
| 1974        | 604            | 13.2       | 11.9  |
| 1975        | 1,521          | 19.4       | 4.3   |
| 1976        | 3,871          | 206.0      | 77.2  |
| 8.6 mm/hour |                |            |       |
| 1974        | 1,333          | 29.1       | 23.4  |
| 1975        | 3,354          | 39.0       | 8.5   |
| 1976        | 8,514          | 412.2      | 154.6 |

Table 4. — *Populus hybrids at Harbor Springs after three growing seasons*

| Hybrid   | Survival      |           | Height        |           |
|--|---------------|-----------|---------------|-----------|
|  | Not irrigated | Irrigated | Not irrigated | Irrigated |
|  | Percent       |           | cm            |           |
| <i>P. canescens</i> x<br><i>P. tremuloides</i> | 89            | 72        | 61            | 120       |
| 'Raverdeaux'<br>poplar                         | 50            | <1        | --            | --        |

Even though 92 percent of the rooted cuttings and 21 percent of the nonrooted cuttings of 'Raverdeaux' poplar planted on irrigated plots were alive after the first growing season, only 1 percent of the rooted cuttings and none of the nonrooted cuttings were alive after 3 years. Without irrigation, about 50 percent of the cuttings were still alive after 3 years.

The major causes of first year mortality were shading by grass and feeding by defoliators. Trees that survived the first year were girdled by mice. The rank grass that grew on irrigated plots seemed to provide a favorable habitat for both defoliators and mice. Grass was much shorter and less dense in nonirrigated plots.

## Growth

Irrigation has nearly doubled growth of the *P. canescens* x *P. tremuloides* on this site. Irrigated trees average 120 cm in height after 3 years and nonirrigated trees averaged only 61 cm. 'Raverdeaux' poplar survival was so poor that we did not measure its growth.

## SUMMARY AND CONCLUSIONS

The 'Raverdeaux' poplar has demonstrated the greatest response to effluent irrigation. If rainfall is abundant and well distributed throughout the growing season, irrigation is not necessary to establish nonrooted cuttings but it will greatly enhance establishment if moisture deficits occur. Field planting of nonrooted cuttings has not been successful without intensive weed control. But grass and weeds between tree rows probably serve as temporary storage sites for nitrogen and enhance denitrification.<sup>1</sup> Therefore, nitrogen losses associated with clean cultivation need to be evaluated.

*Populus canescens* x *P. grandidentata* grew faster than any of the other selections except 'Raverdeaux' poplar. *Populus canescens* x *P. tremuloides* seedlings were established successfully where neither rooted nor nonrooted cuttings of 'Raverdeaux' poplar were successful. If plantations are not to be cultivated intensively for the first year or two, a hybrid of *P. canescens* with one of the native species would be a better choice than the more demanding 'Raverdeaux' poplar.

Green ash is the only other selection that has demonstrated good survival and growth.

# A SYSTEM FOR PREDICTING THE AMOUNT OF PHELLINUS (FOMES) IGNIARIUS ROT IN TREMBLING ASPEN STANDS

**Robert L. Anderson**, Pathologist  
Northeastern Area State and Private Forestry  
Delaware, Ohio

and **Arthur L. Schipper, Jr.**, Principal Plant Physiologist  
North Central Forest Experiment Station  
St. Paul, Minnesota

**ABSTRACT.**—The occurrence of *Phellinus* (*Fomes*) *igniarius* white trunk rot in 45- to 50-year-old trembling aspen stands can be predicted by applying a constant to the stand basal area with *P. igniarius* conks to estimate the total basal area with *P. igniarius* rot. Future decay projections can be made by reapplying the basal area of hidden decay for each 6 years projected. This paper describes the methods used to determine the constant and how to use it in the field.

have been examined for predictive use but their correlation with white trunk rot incidence was poor. Many stands that were identified as low *P. igniarius* occurrence areas broke up from white trunk rot in the following 10 years.

In view of the volume of aspen in the Lake States and the magnitude of the problem, this study was begun to find a better way to estimate the amount of white trunk rot in aspen stands.

## MATERIALS AND METHODS

Eighteen 45- to 50-year-old trembling aspen stands were examined for incidence of *P. igniarius* decay (Schipper and Anderson 1978). This age class was selected because stand breakup due to *P. igniarius* is usually not a problem in younger stands in the Lake States. Six stands each in Michigan, Minnesota, and Wisconsin were examined. These stands were located in the Ottawa, Chippewa, and Chequamegon National Forests, respectively.

OXFORD: 443.3—172.8 FO:176.1. *POPULUS TREMULOIDES*. KEY WORDS: *Populus tremuloides*, decay, projection.

White trunk rot, caused by *Phellinus igniarius* (L. ex Fr.) Quel., is the most important rot of trembling aspen (*Populus tremuloides* Michx.) in North America. For years, foresters have needed an easy method to estimate the extent of *P. igniarius* rot in trembling aspen stands. Site index, soil, aspect, and a variety of other variables

The examination procedure was to arbitrarily select a starting point 1 chain (20.1 m) in from the edge of the stand to be examined, and to proceed from that point in a cardinal direction along a transect 20 feet (6.1 m) wide. The first 85 trembling aspen trees encountered on the transect were measured for d.b.h., examined for visible *P. igniarius* conks, and tested for hidden decay by taking a core sample at d.b.h.

## RESULTS

Analysis of the data from the 18 stands after d.b.h. had been converted to basal area revealed a relation between the basal area of aspen trees on a plot with visible conks and the total basal area of aspen trees with decay (table 1). The average basal area of trees with visible conks ranged from 2.31 feet squared ( $0.21 \text{ m}^2$ ) in Michigan to 3.31 feet squared ( $0.31 \text{ m}^2$ ) in Minnesota. Hidden decay ranged from 1.16 feet squared ( $0.11 \text{ m}^2$ ) in Michigan to 2.76 feet squared ( $0.26 \text{ m}^2$ ) in Wisconsin. However, when the conversion factor needed to compute the total amount of decay on a plot was determined, we found that the basal area of total decay averaged 1.9 times the basal area of trees with conks, with a standard error of 0.17.

Table 1.—The average basal area and factor determination for the six stands examined on each of the three National Forests

| National Forest | Average basal area of aspen on plots | Average basal area of aspen with conks/plot | Average basal area of hidden decay/plot <sup>1</sup> |
|-----------------|--------------------------------------|---|--|
| Ottawa          | 29.354                               | 2.312                                       | 1.166  |

| Chequamegon     | 29.93                                | 3.176                                       | 2.756  |

<sup>1</sup> Hidden decay factor ranged from 2.89 to 1.01; averaged 1.9 with a standard error of 0.17

## DISCUSSION

In the Lake States, aspen stands older than about 40 years are subject to breakup due to *P. igniarius* decay. Elsewhere, such early breakup is rare. Breakup refers to the physical loss of trees in the stand through loss of wood fiber due to decay and stem breakage during wind storms due to weakening of the stems by decay.

When a stand in the Lake States is about 40 years old, the land manager must be able to predict whether it must be harvested quickly to

salvage the wood before breakup or whether harvest can safely be delayed to allow additional volume increment. Although stands can be examined for *P. igniarius* conks, an average 6 years is required between the time infection occurs and the first conks become visible. Therefore conks only reveal trees that have been infected for a least 6 years. If stands are examined every 10 years or even more infrequently, breakup may occur in a stand thought to be relatively free of decay. By examining trees for visible conks and then estimating total basal area of trees with decay, the general health of the stand at the time of the survey can be determined. By then using the factor for total basal area with decay at present as the basal area of trees with conks 6 years in the future, the land manager can determine whether the stand is approaching breakup or whether it can safely be retained for future harvest. Using the current amount of hidden decay as an estimate of future decay assumes that infection occurs at a constant rate. This may not be a valid assumption and in fact may err toward a higher infection rate than would actually occur.

## ESTIMATION PROCEDURE

1. Determine the basal area of trembling aspen trees with one or more *P. igniarius* conks. At least 10 sample plots should be used per stand, more in less uniform stands (fig. 1).
2. Multiply the basal area of aspen with conks by the factor 0.9 to estimate the amount of hidden decay, then add this basal area to the basal area of trees with visible conks to estimate total decay.
3. Correct present volume for 6 years growth (table 2) and reapply the hidden decay factor to the total basal area with decay determined above. Add this hidden decay basal area to the total basal area with decay to estimate total decay in 6 years.
4. Repeat step 3 for 12 years' growth and estimate the total decay that will be present in the stand in 12 years.
5. Decide whether to harvest now or whether it can be deferred, based on the estimates for decay at present and in 6 and 12 years.

## LITERATURE CITED

Stand 1 has a high amount of decay and is predicted to begin breakup within the next 10 years. Stand 2 has a much smaller amount of decay and is predicted to continue to produce sound wood during the next 10 years. Using these criteria alone, stand 1 would be harvested in the near future and harvest of stand 2 would be deferred until after another survey and decay estimate had been made 10 years in the future. However, in practice the decision to harvest or retain a stand will depend upon stand objectives, markets, and a variety of other management objectives.

## ESTIMATING INFILTRATION RATES FOR A LOESSAL SILT LOAM USING SOIL PROPERTIES

M. Dean Knighton, *Research Plant Ecologist  
Grand Rapids, Minnesota*

**ABSTRACT.** — Soil properties were related to infiltration rates as measured by single-ring steady-head infiltrometers. The properties showing strong simple correlations were identified. Regression models were developed to estimate infiltration rate from several soil properties. The best model gave fair agreement to measured rates at another location.

**OXFORD:** 114.123. **KEY WORDS:** Bulk density, organic carbon, ground cover, pore volume, modeling.

Land-use practices affect soil properties that, in turn, are related to infiltration rates and overland flow (Sartz 1970). A knowledge of these relations is particularly important if land-use is changing and overland flow and erosion are serious problems. These conditions exist in the Driftless Area of southwestern Wisconsin, northeastern Iowa, and southeastern Minnesota (Hays *et al.* 1949). Inferences about hydrology are often drawn from measured soil properties because direct hydrologic measurements are difficult, expensive, and time-consuming to obtain. The present study was undertaken to improve our ability to make inferences concerning small agricultural watershed response to infiltration in the Driftless Area when only soil properties are measured. Infiltration rates on different soils were measured to find which soil properties most affect infiltration on abandoned hay meadows. A model was then developed to relate soil properties to infiltration rate.

Steady-head infiltration using single-ring infiltrometers may be expected to closely parallel conditions in settling basins where Swartzen-druber and Huberty (1958) successfully modeled infiltration rates so I used their model as a basis for the present study.

It is:

$$F = AT^B \quad (1)$$

where F is cumulative infiltration in mm, A and B are constants, and T is time elapsed in minutes. The instantaneous infiltration per unit time interval (f) may be written:

$$f = ABT^{B-1} \quad (2)$$

where A is numerically equal to the mean rate for the first unit time interval and B is an expression of curvature. The magnitude of B indicates how well the infiltration rate holds up under continuing infiltration. A and B reflect different aspects of the infiltration process and, therefore, may be affected by different soil properties. Soil properties related to A and B were identified and prediction models were developed for each constant.

## METHODS

Infiltration rates were measured with single-ring steady-head infiltrometers on abandoned hay meadows on the Coulee Experimental Forest in southwestern Wisconsin. Twenty sites were selected (Knighton 1977). The soils were Fayette

and Dubuque silt loams (*Typic hapludolf*) of loessal origin and were positioned on broad ridges overlying a fractured dolomitic caprock. Hay had not been harvested from the sites for 3 years and the predominant vegetation was alfalfa (*Medicago sativa* L.). Cumulative infiltration was measured at each site with three infiltrometer rings. Two-hour infiltration runs were made simultaneously for all three rings while maintaining a steady-head of 4 cm (1.6 in.) (Harris 1972). One sample of the surface 4.3 cm (1.7 in.) of soil was taken adjacent to each ring to determine bulk density, organic carbon content, air-filled pore space, water content, and texture. Infiltration and soil property data were averaged for each site. Ground cover was sampled at each site using 10 settings of a 10-point frame (Goodall 1952) on a line transect. Point strikes were classed as follows: (1) bare, (2) litter, (3) alfalfa, (4) forb, or (5) grass.

The infiltration constants in equations (1) and (2) were determined for each site using the measured cumulative mean curves. Points along the mean curve were then used in a least squares analysis of the log transformation of equation (1):

$$\log F = \log A + B \log T. \quad (3)$$

The resulting constants for each site were examined by multiple linear regression analysis using the constant as the dependent variable and soil and cover factors as independent variables. Significant correlations were noted and the regression models that best predicted A and B were determined (Draper and Smith 1966).

To test the regression model selected, actual and predicted infiltration curves were compared from data taken at a site 6 km (10 miles) away on a field with a Fayette silt loam soil that had been abandoned for 6 years (Harris 1972). Infiltration rates

at this site were measured with single-ring steady-head infiltrometers identical to those used in the present study.

## RESULTS

The infiltration constant A was negatively correlated ( $\alpha = 0.01$ ) with soil bulk density and positively correlated ( $\alpha = 0.05$ ) with air-filled pore volume (table 1). These properties reflect how quickly water enters the soil. Bulk density has long been used to indicate the hydrologic condition of soils (Parr and Bertrand 1960) and it is evidently important for the soils considered in the present study. Air-filled pore volume is related to bulk density (Knighton 1977) and reflects a similar hydrologic condition.

The infiltration constant B was significantly correlated ( $\alpha = 0.05$ ) with several properties that reflect the capability of the soil to maintain high infiltration rates (table 1). Organic carbon content, for example, is related to the structural stability of the soil and it increased with B. The density of alfalfa cover and litter cover were also significantly correlated ( $\alpha = 0.01$  and  $\alpha = 0.05$ , respectively) with B. However, the relation decreased with alfalfa and increased with litter cover which suggests that the invading herbaceous vegetation (primarily grass) encourages higher infiltration rates. The constant B was significantly ( $\alpha = 0.01$ ) related to soil moisture content and the relation was positive. This is consistent with the definition of B in that the wetter a soil is at the onset of infiltration the less change there will be in infiltration rate as wetting continues. The opposite is reflected in the negative correlation with air-filled pore space.

Table 1. — Simple linear correlation coefficients for infiltration constants and soil properties (only those soil properties that significantly related to at least one infiltration constant are reported)

| Infiltration constant | Simple correlation coefficient |                   |                    |                    |                    |                   |
|-----------------------|--------------------------------|-------------------|--------------------|--------------------|--------------------|-------------------|
|                       | Bulk density                   | Organic carbon    | Water filled pores | Air filled pores   | Alfalfa cover      | Litter cover      |
| A                     | <sup>1</sup> -0.77             | 0.23              | -0.18              | <sup>2</sup> 0.49  | -0.28              | -0.10             |

<sup>1</sup>Significant at  $\alpha = 0.01$ .

<sup>2</sup>Significant at  $\alpha = 0.05$ .

# THE MODEL

As expected the soil properties were correlated with each other, thereby limiting the number that provided significant information in each model. Also, some variables that were not significant in simple correlation with the constants A and B did provide important information in the multiple regression models. The best model for estimating A included bulk density, clay content, and moisture content (table 2); however, similar results were obtained by deleting either clay content or moisture content. The best model for estimating B included organic carbon content and moisture content (table 2). The standard error was reduced when clay content was used in place of organic carbon content.

The infiltration model, using estimated values for A and B, closely estimated the infiltration curve at the test site (fig. 1, table 3).

|                                 | II                      | 33.743       | -25.758        | -       | .216     | -      | .80                        | 2.267  |
|                                 | III                     | 32.590       | -22.584        | -       | -        | .0710  | .78                        | 2.386  |
| B                               | I                       | 0.348        | -              | 0.111   | -        | .00734 | .74                        | 0.0696 |
|                                 | II                      | .387         | -              | -       | .00802   | .00841 | .71                        | .0726  |

The range of soil properties used to construct the model were as follows:

| <i>Soil Property</i>   | <i>Range</i>     |              |
|------------------------|------------------|--------------|
| Bulk density           | 0.94 - 1.44 g/cc |              |
| Total pore space       | 43               | - 61 percent |
| Vacant pore space      | 7                | - 40 percent |
| Water-filled porespace | 17               | - 38 percent |
| Organic carbon         | 2                | - 3 percent  |
| Texture                |                  |              |
| Clay                   | 15               | - 29 percent |
| Silt                   | 60               | - 71 percent |
| Sand                   | 11               | - 15 percent |
| Cover                  |                  |              |
| Alfalfa                | 8                | - 50 percent |
| Forb                   | 0                | - 32 percent |
| Grass                  | 4                | - 60 percent |
| Litter                 | 8                | - 42 percent |
| Bare                   | 0                | - 46 percent |

## APPLICATION

The procedure for estimating infiltration rate is as follows:

1. Select the appropriate models for estimating the constants A and B from table 2 depending on what soil properties have been measured on the sites in question.
2. Estimate A and B using the regression coefficients from table 2. For example, using Model I, the equations would be:

$$A = 33.185 - 29.699 (\text{bulk density}) + 0.281 (\% \text{ clay}) + 0.124 (\% \text{ moisture})$$

and

$$B = 0.348 + 0.11 (\% \text{ organic carbon}) + 0.00734 (\% \text{ moisture}).$$

3. Substitute estimated A and B in equation (2) to calculate infiltration rate in mm/min.
4. Plot the results for several areas and compare.

This model is intended for use in estimating the effect of changes in soil properties on infiltration rate and should be used only if soil properties are within the range of those used in constructing the model. Infiltration rates will vary greatly within a watershed and the estimated value will only approximate the mean. These estimated rates are for infiltration by a steady-head single-ring infiltrometer. Final rates may be as much as 10 times

those for a sprinkling infiltrometer on similar soils (Green *et al.* 1964). Similar differences could be expected when comparisons are made to precipitation infiltration rates.

**ABSTRACT.** — Three methods of measuring height growth in field plantings are compared.

OXFORD: 522.522.2. **KEY WORDS:** embossing tape, bamboo sticks, meter stick.

Three devices for measuring tree height growth were compared for accuracy: embossing tape, bamboo sticks, and a standard meter stick. The bamboo sticks were used in a prior study (Rudolph 1964), but the use of embossing tape has not been previously described in the literature.

### METHODS AND MATERIALS

The study was done in a jack pine plantation near Rhineland, Wisconsin. Heights were measured weekly for each method on 60 trees.

Before the growing season, we inserted a stainless steel pin into the terminal shoot of each tree 20 to 25 cm below the bud to serve as a reference mark for all three measurement methods. A second pin was inserted about 30 cm below the first pin as an undisturbed reference point to obtain a pre- and post-season measurement for total seasonal growth. This accumulated seasonal growth measurement served as a control. The three measuring devices were prepared and used as follows:

1. *Embossing tape.* — A strip of embossing tape about 90 cm long was attached to the base of a

lateral branch 15 to 25 cm below the terminal bud by exposing a portion of the adhesive surface, wrapping it around the lateral branch, and adhering the two adhesive surfaces together (fig. 1). This joint was further secured by stapling. Where large amounts of growth occurred, more tape was added by sticking and stapling. Weekly growth was marked by stretching the tape taut in a vertical position parallel to the leader and punching a hole in the tape opposite the tip of the leader with a tool made from an ordinary laboratory forceps.

2. *Bamboo stick.* — A thin bamboo stick was taped to the main stem of each tree with 3M<sup>1</sup> bonded tape so that the stick extended well above the leader. A coping saw was used to mark the stick each week at the tip of the terminal bud.

3. *Meter stick.* — For the meter stick, measurements were taken each week from the reference pin to the tip of the terminal bud and recorded.

The authors took turns recording weekly measurements to eliminate bias. Total time for set-up, field measurements, and raw data work up to summary stage was 1,022 minutes for the meter stick, 938 minutes for the bamboo sticks, and 742 minutes for the embossing tape.

<sup>1</sup>Mention of trade names does not constitute endorsement of the products by the USDA Forest Service.

Figure 1. — Schematic diagram showing use of embossing tape to obtain growth measurements.

## RESULTS AND DISCUSSION

**Weekly growth.** — In comparing mean weekly growth for all 60 trees by correlation coefficients and paired "t" tests, the meter stick method served as the control against which the other methods were tested. The growth data showed that the three methods were highly correlated (0.999), for both the bamboo stick and embossing tape when compared with the meter stick method. The paired "t" test showed no significant differences between methods. Hence, any of the three methods is technically acceptable and the choice of method should be based on time or cost.

**Seasonal growth.** — In comparing total seasonal growth, the pre- and post-seasonal measurements for total growth using the undisturbed pin served as the control. These data showed a high correlation with all three methods (table 1). The paired "t" test, however, showed the meter stick method as the only one not significantly different from the control at the 0.05 percent level. A coefficient of variation of overall means of all methods was approximately the same.

Table 1. — Accuracy of measurements using the three tools

| Tool           | Mean total height<br>for all trees<br>mm | "t" value          | Coefficient of<br>variation of x<br>percent |
|----------------|--|--------------------|---|
| Meter stick    | 492.8                                    | 2.067              | 9.23  |
| Bamboo stick   | 499.0                                    | <sup>1</sup> 3.912 | 9.38  |
| Embossing tape | 499.5                                    | <sup>1</sup> 2.669 | 9.17  |
| Control        | 494.9                                    | --                 | 9.44  |

<sup>1</sup>Significant at 0.05 percent level.

The meter stick underestimated the true value by about 0.05 percent, where as the bamboo stick and embossing tape overestimated the true values by 0.9 and 1.0 percent. The paired "t" test showed the meter stick method to be more precise, but this test is extremely sensitive to variation in paired observations and should not influence the decision on which method to use.

Stretching of the embossing tape could be partly responsible for the slightly larger error associated with this method. However, we feel this method has advantages such as saving in time and manpower, less damage to trees, and ease of application. Moreover, the tape can be pre-labeled with all identification, can easily be added to if large amounts of growth occur, and can easily be stored at collection time.

The bamboo stick method resulted in occasional loss of terminal shoots due to cuts from the saw, or by girdling with the tape or ribbon used to secure the stick to the tree. Breakage of the sticks from too deep a cut by the saw was yet another problem.

The bamboo stick and embossing tape methods also offer the advantage of requiring only one person to obtain the measurements.

Costs of materials were not compared but we feel the time and manpower saved by using the embossed tape method would compensate for any difference in cost of materials.

## HERBICIDE TRIALS IN INTENSIVELY CULTURED POPULUS PLANTATIONS IN NORTHERN WISCONSIN

Daniel A. Netzer, Forestry Technician  
and Nonan V. Noste, Research Forester  
Rhineland, Wisconsin

ABSTRACT.—*Populus* had good survival and growth when planting sites had been treated with linuron, a pre-emergent herbicide, alone or in combination with paraquat, a post-emergent herbicide. The herbicide treatments that are most effective in intensive culture are discussed.

OXFORD: 441—414.1:238:236.1. KEY WORDS: Competition, pre-emergent, post-emergent, hardwood cuttings, weeds.

This publication reports research involving pesticides. It does not contain recommendations for their use, nor does it imply that the uses discussed have been registered. All uses of pesticides must be registered by appropriate State and/or Federal agencies before they can be recommended.

**CAUTION:** Pesticides can be injurious to humans, domestic animals, desirable plants, and fish or other wildlife—if they are not handled or applied properly. Use all pesticides selectively and carefully. Follow recommended practices for the disposal of surplus pesticides and pesticide containers.

Using intensive plantation culture to increase yields is one way to help meet the rising demand

for wood products. Many practices have already been found to increase yield of intensive culture plots—use of genetically improved stock, fertilization, irrigation—but further investigations may discover even more ways to increase biomass production. Although the use of herbicides to control weeds and thereby increase production has already been proven (Erdmann 1967, Erdmann and Green 1967, von Althen 1970), the toxic effect of specific chemicals and the proper application rates are not known for *Populus*.

Cram (1967) recommended local testing of herbicide treatments and other adaptation for the specific sites that may be used in intensive culture. Information should be developed locally on the different levels of treatment intensity by using both a post-emergent in combination with a pre-emergent herbicide and by varying the application rates.

We conducted a study to evaluate the effects of 12 herbicide treatments on competing vegetation and growth of *Populus* 'Tristis #1' (*Populus balsamifera* L. x *P. tristis* Frisch.) cuttings. The locations represent sites where intensive culture plantations may be established in future studies. These included a clearcut forested site, an abandoned farm field with established sod, and a well-cultivated field.

## PROCEDURES

Sodded and clean-tilled sites were located on the Hugo Sauer Nursery in Rhinelander, Wisconsin, and the clearcut site was located on the Harshaw Experimental Farm approximately 10 miles west of Rhinelander. Three pre-emergent herbicides were tested—simazine (Princep),<sup>1</sup> linuron (Lorox), and dichlobenil (casoron)—as well as two post-emergent herbicides—paraquat (Ortho Paraquat) and glyphosate (Roundup). Dichlobenil was applied in granular form and raked into the soil surface. Simazine and linuron were mixed in a 2-gallon sprayer in the amounts required to cover one plot. Glyphosate and paraquat were applied in a tank mix with the pre-emergents in the first year and direct sprayed in the second year. Pre-emergent herbicides were applied prior to planting. Post-emergent herbicides were applied in combination with the pre-emergents the first season and alone the second season. The codes that will be used in the rest of the publication for the 12 herbicide treatments are shown in table 1.

Each herbicide treatment was replicated 3 times on each of the 3 sites in a randomized block design. Thirty-six 4- by 4-foot plots with a 4-foot buffer strip were established at each site (on a 44- by 44-foot area) and 16 trees were planted on each plot at 1- by 1- foot spacing. Before planting the nursery site was rototilled, the sod site was disked

<sup>1</sup>Mention of trade names does not constitute endorsement of the products by the USDA Forest Service.

and rototilled, and the clearcut site was prepared by clearing all woody vegetation and clipping volunteer sprouts. The herbicides were first applied on June 28, 1974.

*Populus* cuttings (6 to 8 inches long and 3/8-to 5/8-inch diameter) from the previous year's growth were collected in April 1974 and stored in a freezer until they were planted on July 1 to 3, 1974. Cuttings planted on the nursery and sod sites were unrooted, but cuttings planted on the aspen site were prerooted in styrofoam blocks using a 1-1-1 media of soil-sand-peat because they could not be watered after planting. The nursery site was irrigated continually as needed throughout the growing season and the sod site was hand watered for 2 weeks. Cuttings on the clearcut site received a cup of water at planting.

Height, diameter (1 inch above the ground), and survival were determined at the end of the growing seasons in 1974, 1975, and 1976. Before the first frost in 1974 and 1975, weeds from each plot were clipped, separated by genus, oven-dried, and weighed. Two-way analysis of variance, regression analysis, and Duncan's new multiple range test (Li 1964) were run at the 5 percent significance level.

## RESULTS

Analysis of variance showed that there were significant treatment effects on survival on the nursery site in 1975, the sodded site in 1975 and 1976, and the clearcut site in 1975, and on height on the sodded site in 1976. Correlations of *Populus*

<sup>1</sup>Application rates refer to total rather than active ingredient of the herbicide.

height and survival with weights of the competing vegetation by species were nonsignificant.

Three treatments involving moderate application rates of linuron alone and in combination with paraquat or glyphosate showed promise for eventually improving biomass production. Cuttings raised under the treatment of 4 lb. acre of linuron alone (L4) or in combination with 1/2 lb. of paraquat applied in the first year (L4,P1/2,1) or first and second year (L4,P1/2,2) generally had superior survival. Survival in 1976 for these treatments was 33, 40, and 38 percent, respectively, on the sodded site (table 2). Treatment (L4) resulted in 90 percent survival in 1976 on the nursery site compared to 81 percent for treatment (L4,P1/2,1) and 71 percent for treatment (L4,P1/2,2). In 1976, survival on the clearcut site was 31 percent for treatment (L4) contrasted to 31 percent (L4,P1/2,1) and 42 percent for treatment (L4,P1/2,2). Treatments (L8), (S2), and (L4,G3,2) also resulted in good survival of the cuttings.

Low dosages of linuron and simazine gave better results than high dosages, possibly because of a toxic affect. Surprisingly, survival was highest on the nursery control plots in both years. This

<sup>1</sup>See table 1 for explanation of treatment description codes.

<sup>2</sup>Letters following the means indicate differences that are significant at the 95 percent probability level.

<sup>3</sup>No significant differences at 0.05 level of confidence.

may indicate either a herbicide toxic effect or no real competition from the small amount of vegetation present on this site.

Treatments (L4), and (L4,P1/2,1) resulted in superior height growth (table 3). Treatment (S4,P1/2,2) also gave good results as did treatments (L4,P1/2,2) and (L4,G3,2). Height growth was 43 cm in treatments (L4), (L8), and (L4,P1/2,1) on the sodded site and was 40 cm in treatment (S4,P1/2,2). On the clearcut site treatment (L4), (S2), (L4,P1/2,1), and (L4,P1/2,2) gave good height results—41 cm, 53 cm, 50 cm, and 41 cm, respectively. On the nursery site the treatments (L4), (L8), (S2), and (L4,P1/2,2) resulted in heights of 233 cm, 224 cm, 240 cm, and 246 cm, respectively.

The weed species present on the control plots of the three sites in 1974 are shown below.

The weed species present on the control plots of the three sites in 1974 are shown below.

## DISCUSSION

Compared to the control, herbicide treatments improved survival and growth on the sodded site, had no effect on the clearcut area, and possibly had an adverse effect in the nursery. Apparently the thorough tilling on the nursery site eliminated the need for weed control after planting. Linuron

at 4 lb/acre on the sodded site increased survival, as did the additional use of paraquat through this contribution is small. Simazine increased survival on the clearcut site. Treatments (L4), (L4,P<sub>1/2</sub>,1), (L8), (L4,P<sub>1/2</sub>,2), and (L4,G3,2) showed consistently good results. For the most part these are combinations of linuron with a post-emergent herbicide. The use of simazine with the post-emergent glyphosate also increased survival and height growth.

**ABSTRACT.**—Describes the extent of forest land resources in Illinois and estimates their availability for timber and recreational uses using both conventional definitions of forest land and the broader concept of forest and associated land.

OXFORD: 619.0:905.2(773). **KEY WORDS:** Timber supplies, recreational use, Illinois, resource availability, private woodlands.

Although recent statistics on timber stocking, growth, and harvest are available throughout the United States, the volumes of timber actually available to supply the nation's needs are not precisely known. Various economic, social, technical, and institutional factors can have an important impact on availability of timber supplies. Availability is a particularly crucial issue in States like Illinois where most of the timber resource is in small, private tracts. Owners of such forest land have a wide range of management objectives that are often unrelated to the production and sale of wood products.

It is even more difficult to give the availability of all forest-related resources including wood, water, recreation, erosion control, wildlife, and aesthetics. Conventional definitions (USDA Forest Service 1973) of forest land<sup>1</sup> and commercial forest land<sup>2</sup>, which include the provision that the land be at least 10 percent stocked with trees, seem unduly restrictive if all forest-related resources are to be considered.

The purpose of the present paper is to provide an initial realistic, if somewhat imprecise, view of

availability of forest-related resources in Illinois using existing resource data and information already available from various woodland owner studies. Forest and associated lands include not only the conventionally-defined forest lands, but also all noncommercial farms, unimproved pasture, and brush lands. The acreage of forest and associated lands more closely approximates the total acreage available for production of forest and forest-related goods and services.

<sup>1</sup>*Forest land* is defined as land at least 10 percent occupied by forest trees of any size, or formerly having had such tree cover, and not currently developed for nonforest use. The minimum area for classification of forest land is 1 acre. Roadside, streamside, and shelterbelt strips of timber must have a crown width at least 120 feet wide to qualify as forest land. Unimproved roads and trails, streams, or other bodies of water or clearings in forest areas are classed as forest if less than 120 feet in width.

<sup>2</sup>*Commercial timberland* is defined as forest land producing or capable of producing crops of industrial wood and not withdrawn from timber utilization. Areas qualifying as commercial timberland have the capability of producing in excess of 20 cubic feet per acre per year of industrial wood in natural stands. Currently inaccessible and inoperable areas are included, except when the areas involved are small and unlikely to become suitable for production of industrial wood in the foreseeable future.

## CONVENTIONALLY DEFINED FOREST LAND RESOURCES

The most current data (USDA Forest Service 1973) on the forest land area in Illinois were based on an updating of a survey (Essex and Gansner, 1965) completed in 1962. The basic purpose of the survey was to inventory timber. In 1970 Illinois contained 3,786 thousand acres of forest land, 3,677 thousand acres commercial and 109 thousand acres noncommercial. If one allows for the fact that commercial forest land on the Shawnee National Forest increased by 13 thousand acres (presumably transferred from the private sector) since the 1973 publication, the breakdown of ownership is as follows:

| Ownership             | Commercial forest            | Noncommercial forest |
|-----------------------|------------------------------|----------------------|
|                       | land acreage                 | land acreage         |
|                       | ----- (thousand acres) ----- |                      |
| Private-nonindustrial | 3,382                        | 79                   |
| National forest       | 227                          | 27                   |
| Other Federal         | 41                           | --                   |
| State                 | 11                           | 3                    |
| Forest industry       | 16                           | --                   |
| Total                 | 3,677                        | 109                  |

With the exception of 3.5 thousand acres of national forest land which is reserved for experimental forests, research plots, developed recreation sites, and administrative sites, most of the Federal, State, and forest industry commercial forest land in Illinois (a total of 291.5 thousand acres) can realistically be considered as available for timber harvest consistent with multiple-use management principles.

An estimate of the availability of private, nonindustrial commercial forest land was made by reviewing various woodland owner studies that obtained information relating to availability. Neuzil<sup>3</sup> in a study of owners who had recently acquired woodlands in a 7-county area of Illinois found that 45 percent planned to make commercial timber sales; a recent computation from the Neuzil study showed these owners controlled about 50 percent of the sampled acreage. Beazley and Holland (1973) found that 40 percent of the woodland owners in a central county (Fulton) and

<sup>3</sup>Neuzil, Michael A. 1970. *A study of the new landowner in Southern Illinois*. 66 p. Unpublished M.S. thesis on file at Southern Illinois University, Department of Forestry, Carbondale, Illinois.

30 percent of those in a southern county (Jackson) planned to sell timber. Recent estimates from the original data showed that the Jackson County owners planning sales controlled about 40 percent of the woodland acreage and the Fulton County owners about 50 percent.

Considering these data and the fact that some owners in the Beazley-Holland study who did not plan sales looked on their woodland as a reserve convertible to cash in case of a special need, roughly 50 percent or 1,691 thousand acres of the private, nonindustrial commercial forest land in Illinois is available for timber production. When this figure is added to the 291.5 thousand acres of Federal, State, and industry-owned land that is available, a total of 1,982.5 thousand acres, or about 54 percent of the States' commercial forest land is obtained. (Noncommercial forest land is assumed to be unavailable for timber production.)

The preceding studies looked at harvest objectives at a single point in time. A more long-run view may yield different results. A recent Delaware study (Turner *et al.*, 1977) concludes that at some time most forest crops will come under the control of an owner who will consider harvesting.

The forests of Illinois also provide opportunity for various forms of outdoor recreation. Callahan, *et al.* (1974) estimated that about 95 percent of the Shawnee National Forest was available for recreation. Applying this percentage to the current national forest acreage of 254 thousand acres gives an availability figure of 241 thousand acres. Assuming a similar percentage for other Federal, State, and industry forest land, 67 thousand acres may be added, giving a total of 308 thousand acres of public and industrial forest land available for recreation in Illinois.

Two Illinois studies provided a basis for estimating the availability of private, nonindustrial forest land for recreation. Neuzil found that 38 percent of the new woodland owners in a 7-county area of southern Illinois allowed some use of their land for outdoor recreation by the public. McKibben<sup>4</sup> reported that 42 percent of rural

<sup>4</sup>McKibben, William G. 1968. *A study of the outdoor recreation policies of the private landowners in the Shawnee Hills Planning Region, Illinois*. 59 p. Unpublished M.S. thesis on file at Southern Illinois University, Department of Forestry, Carbondale, Illinois.

landowners owning 160 acres or more in southern Illinois allowed some public recreational pursuits on their land.

The estimates by Neuzil and McKibben were reduced because of several factors. First, a portion of the landowners in both the above studies restricted use primarily to friends, relatives, and neighbors. Second, McKibben found that those landowners with larger farms were less inclined to allow public recreation. Finally, both Neuzil and McKibben studied landowners in counties with limited urban development. We scaled their estimates downward to 30 percent since it seemed likely that other owners close to large urban areas would be more reluctant to allow public recreational use. Applying this percentage figure yields a total of approximately 1,014.6 thousand acres. Table 1 summarizes the availability of "conventionally defined" forest land in Illinois.

<sup>1</sup>As defined by the Forest Service (1973).

<sup>2</sup>Fifty percent of private-nonindustrial commercial forest land.

<sup>3</sup>Thirty percent of total private-nonindustrial forest land.

<sup>4</sup>Commercial national forest land minus 3,500 acres reserved for nontimber uses.

<sup>5</sup>Ninety-five percent of total forest land in each ownership category.

## FOREST AND ASSOCIATED LAND RESOURCES

Beazley (1965) estimated that roughly 9 million acres, or 25 percent of the State land area, is "forest and associated land";<sup>5</sup> (including "conventionally-defined forest land", brush lands, unimproved pasture, and land on noncommercial farms—in short all nonurban, nontransportation or service, and noncommercial agriculture lands) and provide the "forest-related resources" mentioned earlier. This is more than twice the

"conventionally-defined forest land" estimates of 10.5 percent of the State, and closely approximates the total of what assessors call "unimproved land". Beazley maintained that these lands have an essential unity in producing the forest-related resources mentioned earlier, and that they are sufficiently similar to be considered as a group for multiple-use, integrated land use planning and management. Further studies showed that these lands could be accurately determined from aerial photos, and that they show a much more extensive, unified, less fragmented, spatial arrangement for planning and management than do "conventionally-defined forest lands". Table 2 summarizes the ownership and availability of "forest and associated land" in Illinois using the same estimated availability percentages of 50 percent for timber and 30 percent for recreation that were used for conventionally-defined forest land.

## IMPROVING AVAILABILITY ESTIMATES

The availability figures presented here are based on owner attitudes at a single point in time resulting from a given set of economic, technological, and social circumstances. Obviously the circumstances and owner attitudes change and new owners with new attitudes arrive on the

<sup>5</sup>Beazley arrived at his estimate as follows: (1) The ratio of land in commercial farms to all land in all farms was first determined. Call it "R". (2) The following areas were summed: woodland pastured and not pastured; other pasture, not cropland, or improved pasture; and wasteland (wasteland = "other land" less 2 percent of farm area for buildings and roads). Call this total "W". (3) An estimate of the acreage of actual commercial farm land in commercial farms was then determined by subtracting the proportional amount of "W". That is, commercial land = land in commercial farms - (R x W). An estimate of urban, service and transportation land (6 percent for the State; which varied by counties) was added to commercial farm land to provide an estimate of "urban, service, and (genuinely) agricultural land." (4) The figure for urban, service, and agricultural land area was subtracted from the total land area in each case to arrive at the figure for area in "forest and associated land".

Table 2.—Forest and associated land acreage in Illinois by ownership category and availability for timber harvest and recreational use

(Thousands of Acres)

| Ownership category    | Total forest and associated land | Available for timber harvest | Available for recreation |
|-----------------------|----------------------------------|------------------------------|--------------------------|
| Private-nonindustrial | 8,675                            | 11,691                       | 22,612                   |
| National Forest       | 254                              | 3 224                        | 4 241                    |
| Other Federal         | 41                               | 41                           | 4 39                     |
| State                 | 14                               | 11                           | 4 13                     |
| Forest industry       | 16                               | 16                           | 4 15                     |
| Total                 | 9,000                            | 1,983                        | 2,920                    |

<sup>1</sup>Fifty percent of private-nonindustrial commercial forest lands.

<sup>2</sup>Thirty percent total private-nonindustrial forest and associated land.

<sup>3</sup>Commercial national forest land minus 3,500 acres reserved for nontimber uses.

<sup>4</sup>Ninety-five percent of forest and associated land in respective ownership category.

scene. Data indicating long term trends in owner attitudes are generally unavailable but recent studies indicate that change can occur quite rapidly and over longer time periods most owners will harvest timber when it become economically feasible to do so. For recreation, however, a trend to closing more and more private land to public use seems clear. In both cases frequent monitoring of availability to indicate changes and trends would be desirable.

## SUMMARY AND CONCLUSIONS

Resource statistics based on conventional definitions of forest land can be misleading, particularly in States like Illinois where most of the forest land is in small parcels owned by a diverse group of private, nonindustrial owners. We estimate that no more than 50 percent of the conventionally-defined, private, nonindustrial forest land is actually available for timber harvest and only about 30 percent for recreational uses. These figures could be higher over the long run for timber but availability for recreation is likely to decrease if past trends continue and new public incentive devices are not adopted.

There is more land available to the public for forest recreation on the greater acreage of "forest and associated land", but not necessarily more timber, at least in the short run.

Although more and more small private owners are not harvesting their timber for aesthetic or noneconomic reasons, the *primary* reason that owners of small private tracts are not selling their timber is because they think their tracts are too

small or the trees too small and low in quality (Quinney, 1962) to be worth harvesting.

"Forest and associated lands" as defined earlier have a greater potential for producing a full range of forest-related resources than the smaller, more narrowly defined "forest lands" and provide a useful concept for resource planning. To encourage owners to make these lands available for timber, recreation, and other resources, a comprehensive statewide or regionwide management plan with incentives and cooperative agreements is needed.

Fear of liability for injuries and damage to property has prevented owners from making more "forest and associated land" available for public recreational use. Still, about 10 percent of owners not allowing public recreational use responded favorably to leasing programs, and 30 percent were interested in cooperative agreements with their neighbors to allow public use of their lands.

**ABSTRACT.**—The pine needle rust of jack pine on the Little Sioux Burn in northeastern Minnesota infected large-leaf aster but not goldenrod. The rust was most severe when asters were abundant on the plots. Less than 10 percent of the jack pine were infected over a 3-year period when asters were more than 10 feet (3.05 m) from the mil-acre plots.

OXFORD:172.8:415.15(776). **KEY WORDS:** *Coleosporium asterum*, red pine, aster, goldenrod, races.

Early literature, including Arthur (1934), indicates that both goldenrod, *Solidago* sp., and aster, *Aster* sp., are alternate hosts for the pine needle rust, *Coleosporium asterum* (Diet.) Syd. After inoculating alternate host plants of both genera, Hedgcock and Hunt (1922) suggested that, in the eastern United States *Coleosporium solidaginis* (Schw.) Thum (*C. asterum*) either included two races each infecting only one of the alternate host genera or else should be considered as two species of rust. In the western United States, however, Weir and Hubert (1916) obtained infection of both alternate host genera from single sources of inoculum and Weir (1925) repeatedly transferred

the rust from *Aster* to *Solidago* and from *Solidago* to *Aster* by means of urediospores. Apparently no further attention was given to this problem until the studies by Nicholls *et al.* (1968) in Wisconsin. They suggest that there are at least three forms or races of *C. asterum*, one specific to *Solidago*, another specific to *Aster*, a third occurring on some species of both genera. They also suggest that infection of red pine, *Pinus resinosa* Ait., jack pine, *P. banksiana* Lamb., and Austrian pine, *P. nigra* Arnold, in Wisconsin is limited to the form or race of the rust found on *Solidago* sp.

Our purpose here is to identify the alternate host of the needle rust on jack pine on the "Little Sioux Burn" in northeastern Minnesota and to present further evidence suggesting that *C. asterum* is composed of a complex of races or forms.

In May 1971, a large fire, the Little Sioux Fire, burned several thousand acres on the Superior National Forest in northeastern Minnesota. On those sites occupied by jack pine or aspen, *Populus tremuloides* Michx., abundant natural regeneration occurred. In the summer of 1972, experiments were set up to determine the

influence of diseases on jack pine seedling survival on the burn. Two sites were selected for study, one a good jack pine site on deep sandy soil, the other a poor site on very shallow soil overlying bed rock. On each site 100 mil-acre sample plots were set up along a transect, across the site, approximately one-fourth mile in length. Plots were examined in June 1973, 1974, and 1975.

Needle rust infection was abundant on both sites. This posed two interesting questions: Although *Aster macrophyllus* L. was abundant on both sites, no *Solidago* sp. were found on any of the plots. A reconnaissance of both sites in the vicinity of the plots also failed to reveal any *Solidago* sp. This suggested that *Solidago* was not involved and that *Aster* was the alternate host, contrary to Nicholls *et al.* (1968) in Wisconsin. It was also noted that the needle rust infection was not distributed at random. Instead, it was severe on some plots and absent on others.

An analysis was made to determine whether there was any correlation between local abundance of *A. macrophyllus* on and in the immediate vicinity of individual plots and the prevalence of *C. asterum* infection of jack pine on the plots. The results, essentially identical for both sites, suggest a close relation between the presence of aster and prevalence of needle rust on jack pine (table 1). They also indicate that aster must be abundant within a few feet of the jack pine seedlings to cause heavy infection, at least under the conditions that prevailed on the Little Sioux Burn.

Table 1.—Prevalence of needle rust infection in relation to presence and abundance of aster

The information obtained in the field suggested that it would be desirable to follow-up with a greenhouse inoculation study using inoculum collected from several locations in the Lake States region. *Aster macrophyllus* and *Solidago* sp. were potted in the fall of 1974 and held over winter in the greenhouse. Pine needles bearing needle rust aeciospores were collected from several locations in early June 1975; three jack pine and one red pine collections were used.

Five aster and five goldenrod plants were inoculated from each aeciospore collection, and incubated. Five aster and five goldenrod plants were incubated without inoculation to serve as controls. The test was repeated a second time using the same aeciospore inoculum and a third time using urediospores produced in the first test. No infection occurred on any of the control plants, and all the results were identical for all three tests on all collections.

Inoculations from two of the jack pine collections (one from the Little Sioux Burn in northeastern Minnesota and the other from a Washburn area in northern Wisconsin) infected aster but not goldenrod. Inoculations from the third jack pine collection (from the Beltrami Island area in northwest Minnesota) infected goldenrod but not aster. The red pine aeciospore collection (from the Chippewa National Forest in north-central Minnesota) also infected goldenrod but not aster.

These results support the conclusion that large-leaf aster is the alternate host for the jack pine needle rust on the Little Sioux Burn. They also indicate that both aster and goldenrod serve as alternate hosts for needle rust on jack pine, but that different forms or races of the rust are involved on each of these alternate host genera. Beyond this, because of the small number of collections tested, more questions are raised than answered.

Are there forms or races of the pine needle rust that can infect eastern species of pines and both genera of alternate hosts as was indicated in the West by Weir and Hubert (1916)? There appears to be no reason why, on some sites, a mixture of forms or races, one on goldenrod the other on aster, could not result in mixed infection on a single pine or even a single needle. Proof would

require alternate host inoculation studies with aeciospore in oculum form single aecium sources on pine needles to avoid mixed inoculum and assure that the rusts tested are in fact pathogenic on pine. Uredia arising from successful inoculations should then be tested for transfer between alternate host genera as was done by Weir (1925) in the West.

Are there forms or races of the pine needle rust occurring on red pine that use aster as an alternate host? The single red pine isolate tested in this study, plus those by Nicholls *et al.* (1968), are too limited a sample. Testing results from a large number of inoculum sources would be needed to answer this question.

The needle rust fungus has developed forms or races that differ on the alternate hosts. Does it also differ on the pine hosts, i.e., do the races or forms infecting jack pine also infect red pine and the other hard pine species susceptible to needle-rust infection? If the rust called *C. asterum* is composed of "forms or races" that differ, not only in the genera of alternate hosts infected but also in the pine species infected, then it would seem questionable to regard the rust as a single species, unless the various races could interbreed and change. Attempts to answer this question would require pine host range inoculation studies using inoculum originating from known pine and alternate host sources.

To complicate the picture further, it has been shown that *Coleosporium viburni*, which causes a needle rust of jack pine indistinguishable in the field from *C. asterum*, has as its alternate host the Arrow-wood, *Viburnum cassinoides* L., Ouellette (1966).

PULPWOOD PRODUCTION IN THE LAKE STATES

BY COUNTY, 1977

James E. Blyth, *Principal Market Analyst*,  
 and W. Brad Smith, *Associate Mensurationist*

**ABSTRACT.**--This 32nd annual report shows 1977 pulpwood production by county and species group in Michigan, Minnesota, and Wisconsin. Production in these three Lake States inched ahead to 4.74 million cords from 4.69 million cords in 1976.

**OXFORD:** 861.0(77):792. **KEY WORDS:** Residue, Minnesota, Wisconsin, Michigan.

Lake States pulpwood production advanced slightly to 4.74 million cords in 1977 from 4.69 million cords in 1976. Production rose 3 percent in Michigan to 1.59 million cords and 2 percent in Minnesota to 1.33 million cords. Wisconsin output dropped 1 percent to 1.82 million cords.

For every 89 cords cut from roundwood (including chips) 11 cords were derived from mill residue such as slabs, edgings, veneer cores, and chips from those materials. Output from softwood and hardwood residue by State was:

| <i>State</i> | <i>Softwood</i>        | <i>Hardwood</i> |
|--------------|------------------------|-----------------|
|              | Hundred standard cords |                 |
| Michigan     | 208                    | 1,708           |
| Minnesota    | 353                    | 779             |
| Wisconsin    | 480                    | 1,486           |

Production changes were small to moderate for all species. Major increases were for aspen (68,000 cords), soft maple (33,000 cords), and balsam fir (29,000 cords). Lake States hardwood residue procured for pulping rose 38,000 cords. Largest declines in the pulpwood harvest were for elm (55,000 cords) and birch (33,000 cords).

Harvesting increased mainly in Michigan's western Upper Peninsula and southern Lower Peninsula and north-central Minnesota while the major decline was in central Wisconsin.

Top-producing counties were Iron, Delta, and Marquette in Michigan; St. Louis, Koochiching, and Itasca in Minnesota; and Marinette, Oneida, and Forest in Wisconsin.

Pulpmills using Lake States timber in 1977 reported their pulpwood receipts by species groups and State and county of origin. Their cooperation is gratefully acknowledged. Thanks are also due the Michigan Department of Natural Resources for collecting the data from pulpmills in Michigan.

**ABSTRACT.**—Relative distributions of biomass and net primary production among plant components are reported for three tree species and four shrub species common to the northern deciduous forest.

The procedures for selection of samples and the determination of biomass and net primary production have been reported (Crow 1978). The figures presented in tables 1 and 2 were determined from dry weight values.

OXFORD: 161.4:182.46:182.41. **KEY WORDS:** Biomass, birch, maple, net primary production, Wisconsin.

Biomass and production relations for several woody species common to the northern forest were determined as part of a study conducted in the Enterprise Forest near Rhinelander, Wisconsin (Rudolph 1974, Zavitkovski 1977). Four shrubs, *Vaccinium myrtilloides*, *Rubus allegheniensis*, *Corylus cornuta*, *Ilex verticillata*, and three trees, *Acer rubrum*, *Acer saccharum*, *Betula papyrifera*, were sampled. These species represent a spectrum of growth forms and plant sizes. The relative distributions of biomass and production by plant component, with comparisons among species, are reported here.

The obvious differences in proportionalities of biomass and production between *Rubus* and other shrub species can be attributed to its growth form (table 1). From an underground, perennial base, several aerial, biennial stems are produced; these stems were harvested in this study. During the first growing season, the biennial stems (primocanes) are usually unbranched and rarely produce inflorescence; during the second growing season, these stems (floricanes) cease growth but produce a number of short lateral branches, often with terminal inflorescence. Leaves and current twigs accounted for all the biomass of primocanes. Biomass distribution for the floricanes was divided among the first-year stem (36 percent stem and branches), the lateral branches (63 percent leaves and current twigs), and fruit (1 percent).

Among the other shrub species, stem and branch biomass ranged from 64 to 89 percent and current twig and leaf weight ranged from 35 to 11 percent

for the small shrub *Vaccinium* to the large shrub *Ilex*, respectively. For all species, the fraction of dry weight represented by fruit and fruiting bodies was 1 percent or less of the aboveground biomass.

Despite structural differences, the distribution of production among various components was very similar for *Vaccinium*, *Corylus*, and *Ilex* (table 1). Radial growth on stems accounted for only 11 to 18 percent of the aboveground shrub production. The proportions of growth in current twigs and leaves ranged from 82 to 86 percent of aboveground production.

Among the trees sampled, bolewood accounted for 64 to 69 percent of the aboveground biomass, bolebark 8 to 11 percent, branches 16 to 22 percent, and leaves and current twigs 3 to 5 percent (table 2). The distribution of biomass for the two maples corresponded closely for all components. Birch had more biomass in the stem and less in the canopy than did maple.

Distributional differences among species can be explained in part by morphological differences. For example, birch has many short-shoot twigs, each with a cluster of leaves. Minimal apical

| Leaves and current twigs  | 42.1               | 44.5                  | 34.4                     |

growth by these twigs results in less biomass classified as current twigs. The branching habit of birch—few large branches, many short, pendulous branches—could account for the lesser proportions of branch biomass in birch than in the maples.

Size is an important determinant in biomass distribution among components. There was a marked decrease in the proportion of bolebark with increasing stem size, a trend associated with the decrease in the surface-area/stem-volume ratio. Also present was a trend of increasing concentrations of woody tissue with increasing size of a plant. Except for *Rubus*, the percentage of woody biomass and net production increased from the smallest species to the largest species (tables 1 and 2). Net production in stem and branches together ranged from 55 to 66 percent for the trees and from 11 to 18 percent for shrubs (excluding *Rubus*).

The proportions of belowground and aboveground biomass also varied with plant size. The mean belowground/aboveground ratio for aspen, obtained from the excavation of 20 trees between 2 and 8 cm d.b.h., was  $0.24 \pm 0.02$  ( $\pm$ SE). For *Corylus*, a shrub of intermediate size, the mean ratio

was  $1.03 \pm 0.07$  (N=49) and for *Vaccinium*, a small shrub, the mean ratio was  $1.96 \pm 0.32$  (N=7). Other reports of belowground/aboveground biomass ratios for trees ranged from 0.2 to 0.3 for young trees to less than 0.2 for large trees (Ovington 1962), and ratios for shrubs range from 0.6 to 1.8 (Whittaker 1962). The average belowground/aboveground ratio for herbaceous species harvested at Enterprise ranged from 2.98 to 4.79 (Zavitkovski 1976). Thus, 19 percent of the total dry weight for the tree was belowground, compared to 51 percent for the intermediate shrub, 66 percent for the small shrub, and 75 to 83 percent for the herbaceous species.

# EFFECTS OF STOCK REMOVAL RATES ON BELT LOADING FOR ABRASIVE PLANING HARDWOODS

Harold A. Stewart, *Forest Products Technologist,*  
 Carbondale, Illinois

GOVT. DOCUMENTS  
 DEPARTMENT OF AGRICULTURE  
 DEC 1978  
 CLEMSON UNIVERSITY LIBRARY

**ABSTRACT.**—Belt loading increases up to a point and then decreases as stock removal rate increases for red oak and yellow-poplar.

**OXFORD:** 832.16. **KEY WORDS:** Machining, sanding, surfacing, tool life.

Abrasive planing hardwoods precludes knife planing defects and may upgrade the lumber enough to offset the added cost. A common problem with abrasive planing, however, is "belt loading"—the accumulation of waste material on the belt, decreasing its abrasiveness and hence shortening belt life. If belt loading could be eliminated, or at least reduced, abrasive planing of hardwoods would be more efficient.

In a study of abrasive planing ponderosa pine (Stewart 1976), belt loading increased and belt life decreased as depth of cut was increased up to a point. However, as depth of cut was further increased, belt loading decreased and belt life increased until the rate of stock removal caused excessive stress in the belt and greatly reduced belt life. A study was undertaken to determine if the belt-loading pattern for hardwoods is similar to that for ponderosa pine.

## METHODS

Air-dry (12 percent average moisture content) red oak and yellow-poplar boards 3½ inches wide

and 5 feet long were surfaced to a uniform thickness of 7/8 inch. Red oak and yellow-poplar represent high and moderate density hardwoods, respectively.

The red oak was machined at 45-feet-per-minute (fpm) feed rate and six depths of cut (0.005, 0.010, 0.020, 0.040, 0.080, and 0.120 inch). Yellow-poplar was machined at three feed rates (60, 75, and 90 fpm) and the same depths of cut as red oak. The abrasive belts were aluminum oxide, 18 by 103 inches, grit size No. 36. The nominal belt speed was 5,800 feet per minute.

## RESULTS

The belt-loading pattern for both hardwood species did indeed prove to be similar to that for ponderosa pine. Belt loading increased up to 0.040-inch depth of cut at 45 fpm feed rate for red oak and 0.080-inch depth of cut at 60 fpm feed rate for yellow-poplar. (Higher forces developed at lower stock removal rates when planing red oak, hence beltloading for red oak began to decrease at a lower removal rate than for yellow-poplar). Beyond these feed rates and cutting depths belt loading decreased for both species. Apparently, either the depth of cut or feed rate may be increased to reduce belt loading (fig. 1).

## DISCUSSION

Belt loading may be similar to the formation of "built-up edge" (BUE) in metal cutting. The BUE is a result of the normal loads on the tool face leading to adhesion between the chip and tool (Armarego and Brown 1969). The adhesion is probably similar to a pressure weld and/or a result of Van der Waals forces, which cause two surfaces to adhere when they are pressed together. The mechanics of adhesion of sliding systems (Armarego and Brown 1969), such as where the workpiece and tool meet, involves:

1. The tool rubbing a freshly cut surface from the workpiece.
2. Plastic deformation of the workpiece material when forming the chip.
3. High temperature and pressure at the sliding interface of the tool and workpiece material.

The same relation between cutting speed (stock removal rate) and belt loading that we found appears to exist also for metal work (Cook 1966). At very low speeds a BUE may not form. At a relatively moderate, critical cutting speed BUE begins to develop. As the cutting speed increases, more of the BUE is carried away and may disappear.

Other things that reduce belt loading include increasing air velocity for removing waste to reduce pressure between the sliding belt and workpiece (this may also reduce the temperature of the wood) and increasing belt speed which reduces chip load and also reduces belt pressure. However, both these methods require increased energy to maintain the same productivity.

So, for the present at least, it appears that, when abrasive planing hardwoods, belt loading can be reduced and belt life prolonged by using high stock removal rates. Extensive testing will be required to determine the optimum rates and conditions for hardwoods.

ABSTRACT.—Aspen suckers from 1-m-long root cuttings survived and grew better than those from 12.5-cm-long cuttings. Sucker survival and growth were also inversely related to parent root diameter. Discusses the practical implications for aspen management.

OXFORD: 231.5:161.4:176.1. *Populus tremuloides*. KEY WORDS: *Populus tremuloides*, regeneration, propagation, planting, site-preparation.

Suckering is a major regeneration mode of quaking aspen (*Populus tremuloides* Michx.). With rare exception, aspen will not sucker appreciably until (1) the flow of inhibitory auxin from apical meristems to roots is interrupted (Farmer 1962)—which occurs when the bole or roots are severed—and (2) the root temperature is raised above some critical level (Maini and Horton 1966).

Studies have shown that the number of suckers produced is governed by hormones (Eliasson 1971), and that initial sucker growth is dependent on stored carbohydrate reserves (Schier and Zasada 1973, Steneker 1972, Zasada and Schier 1973).

Full growth potential of new aspen sucker stands is further dependent on an intact parent root system. Zahner and Debyle (1965)

found that parent roots of *Populus grandidentata* (Michx.) (especially those distal to the sucker) contributed more to sucker growth than did new roots until about age 25. Sectioning of parent roots appears to reduce sucker growth (Sandberg 1951, Steneker and Walters 1971).

Most quaking aspen suckers arise from parent roots less than 2.5 cm in diameter (Farmer 1962, Maini 1968a, Sandberg 1951), but it is not clear if large-diameter parent roots are poor sucker producers, or if they are simply less abundant.

To determine more about the relations between sucker growth and parent root systems, I outplanted long (1 m) and short (12.5 cm) quaking aspen root cuttings of varying diameter.

Survival, height growth, and biomass of the suckers were measured over a 6-year period, and the feasibility of establishing aspen by outplanting root cuttings was evaluated.

### METHODS

On May 8 and 9, 1972 (about 10 days prior to bud burst), six 1-m root cuttings free of serious injury or defect were taken from one average tree in each of 10 widely separated

mature, well stocked good site aspen stands in Cass and Itasca Counties, Minnesota. Root cuttings from each tree were relatively uniform in diameter but varied significantly between trees. There was no significant correlation of root diameter with any tree characteristic. Three of these six cuttings selected at random were immediately clipped into eight 12.5-cm cuttings to prevent polar redistribution of auxin (Maini 1968b). The cuttings were kept moist and cool during transport, and stored at 4C until outplanted. On May 26, 1972, the outplanting site (a former agricultural field) was prepared with a rototiller. After all fine roots were trimmed for the sake of uniformity, the cuttings were washed, blotted dry, and weighed. Because of within-cutting variation in diameter due to swellings and taper, average diameters were estimated from average cutting weight based on an independently determined relation of 58 g fresh weight per square centimeter cross-sectional area per meter length. Most of the cuttings exhibited sucker primordia, often clustered at swellings. A few primordia had already formed suckers up to 2 cm long. On May 30, the cuttings were planted horizontally at a depth of 2 to 3 cm, lightly mulched with straw to retard moisture loss, and thoroughly watered.

All cuttings from a tree were planted 0.5-m apart in adjacent 1.5-m<sup>2</sup> plots; long cuttings in one plot and short cuttings in the other. The short cuttings were laid end to end to make three 1-m aggregate lengths. Twenty-nine surplus short root cuttings were planted in sand in a greenhouse and automatically watered twice daily.

A maximum-minimum recording thermocouple installed at cutting depth showed the 1972 summer had favorable soil temperatures for sucker initiation (12.7 to 28.6C). Rainfall (26 cm) was generally adequate; however, irrigation (0.4 cm) was needed on both June 27 and July 6. During the first three summers, the plots were hand-weeded. Suckers were counted bi-weekly during 1972, weekly in 1973, and at the end of the 1974-1977 growing seasons. Survivor heights were measured after each summer; d.b.h. was measured in 1977.

The data were statistically analyzed using one-way analysis of variance or multiple regression, as appropriate. Logarithmic or square-root transformations were used to obtain homogeneous variance.

## RESULTS AND DISCUSSION

Suckers began to emerge 14 days after outplanting and continued to come up rapidly through the third week of July (fig. 1). Suckering then quickly decreased. Although the first three suckers arose from the short cuttings, suckers emerged faster from the long cuttings. However, total numbers of suckers on both cutting lengths were equal at the end of the first growing season. Five additional suckers were produced by long cuttings during the second year, while none emerged from the short cuttings. The number of suckers did not vary significantly by cutting diameter, except that fewer were produced on short cuttings greater than 2.5 cm diameter (table 1).

Suckers began to die 20 days after the first ones appeared. Most mortality on short cuttings occurred during the first year. Loss of suckers on long cuttings was more gradual and for the most part was evenly distributed from July 1972 to September 1974. Overall, cutting length significantly affected survival; this was mostly accounted for by the highest survival on long cuttings less than 1.6 cm diameter (table 1). Neither long nor short cuttings greater than 2.5 cm diameter had any survivors.

In the green house, 41 suckers emerged (many more were initiated but did not reach the sand surface) but only 6 survived. Excavation of all these cuttings after 67 days revealed that only the survivors had initiated root systems.

The percentage of long cuttings with suckers declined from 80 percent after the first year to 30 percent after the sixth year, and for short cuttings, from 53 to 17 percent (table 2). These calculations are on a per meter cutting bases. If individual short cuttings are considered ( $3 \times 10 \times 8 = 240$ ), only 2.1 percent of them had surviving suckers after the sixth year.

Figure 1.—Accumulated production and survival of quaking aspen suckers on long and short root cuttings (cutting diameters combined). Note change in seasonal scale after 1973.

Height growth of dominant suckers surviving the study period was significantly greater (5 percent level) for long cuttings (fig. 2). Sucker biomass and d.b.h. after 6 years tended to vary directly with cutting length and inversely with cutting diameter, although not significantly (table 3).

Table 1.—Total aspen sucker production and 6-year survival by cutting length and diameter

| Cutting diameter (cm) | (In numbers per meter) |                | 6-year survival |                |
|-----------------------|------------------------|----------------|-----------------|----------------|

| Mean <sup>2</sup>     | 3.30                   | 3.13           | .40             | .17            |

<sup>1</sup>Values followed by the same letter are not statistically different ( $p < 0.05$ ).

<sup>2</sup>Overall means differ from column means due to unequal number of observations per cutting diameter class.

The sucker production from long and short cuttings supports other findings that sucker production is independent of cutting length (Schier 1978, Steneker and Walters 1971). On the other hand, sucker growth was much better on long cuttings than on short ones, presumably because long cuttings have a greater store of available carbohydrates (Schier and Zasada 1973, Steneker 1972, Zasada and Schier 1973).

| 1.6-2.0               | 280                              | 63             | 2.0                     | 1.1            |
| 2.1-2.5               | 243                              | 159            | 1.9                     | 1.6            |
| >2.5                  | 0                                | 0              | 0                       | 0              |
| Mean <sup>2</sup>     | 389                              | 177            | 2.2                     | 1.5            |

<sup>1</sup>Biomass calculated according to Zavitkovski (1971), based on a biomass index of  $d^2h$ , where  $d$  is dbh (cm) and  $h$  is tree height (m).

<sup>2</sup>Overall means differ from column means due to unequal number of observations per cutting diameter class.

The reason for poorer production, survival, and growth of suckers from cuttings with greater diameters (particularly short cuttings) is not known.

## CONCLUSIONS

This study provided further evidence that disruption of the parent root system can be detrimental to the establishment and growth of aspen suckers. The practical implication is that disking or roller-chopping are questionable practices for regeneration of aspen sucker

stands. The best silvicultural practices in aspen appear to be those that leave the parent root system intact.

Establishment of aspen by planting root cuttings is inefficient because of the extremely low ratio of suckers established per unit length of cutting. Survival of suckers under field conditions is extremely poor, even with site preparation and control of competing vegetation. Efficient greenhouse techniques to vegetatively propagate large numbers of suckers from a minimum of root cuttings have been developed by Starr (1971) and Zufa (1971), although little is known of their survival after outplanting.

## JET DRYING OF SOUTHERN PINE AND DOUGLAS-FIR: EXPLORATORY STUDY

Howard N. Rosen, *Research Chemical Engineer,*  
*Carbonate, Illinois*

GOVT. DOCUMENTS  
DEPOSITORY

MAR 1 1979

CLEMSON  
LIBRARY

ABSTRACT.—Southern pine and Douglas-fir boards, containing both heart- and sapwood and 1.75 inches thick, were jet dried at temperatures from 160 to 400°F and air velocities from 3,000 to 9,000 fmp. Jet drying was more effective for southern pine than for Douglas-fir.

OXFORD: 847.1—087. KEY WORDS: *Pseudotsuga taxifolia*, high temperature, shrinkage, drying defects, softwood.

Because of our success with high temperature jet drying several easy-to-dry hardwoods such as yellow-poplar and silver maple (Rosen 1977a), we felt that two of the most popular commercial softwoods, southern pine and Douglas-fir, could be jet dried. Previous work by the Australian CSIRO Forest Conversion Engineering Group (Anon. 1975) and Koch (1977) showed that green southern pine studs could be dried in less than 14 hours at temperatures to 300°F. On the other hand, reports of high-temperature drying of Douglas-fir have not been as promising. Salamon (1963) found that drying 2- by 8-inch Douglas-fir at temperatures to 225°F increased honeycomb and reduced strength more than conventional drying. So we decided to try jet drying southern pine and Douglas-fir lumber ourselves.

### METHODS

Southern yellow pine and costal Douglas-fir boards, 40 inches long by 3¾ inches wide by 1¾ inches thick, were shipped to our Carbonate Laboratory wrapped in tightly sealed plastic packages.<sup>1</sup> Green specific gravity averaged 0.43 for both species. Immediately before a jet dryer run, three boards were trimmed to 30 inches by cutting 5 inches from each end. One-quarter-inch cross sections were cut from the trimmings of the boards for moisture content determination by oven drying. Boards were not endcoated except for six boards for the final two runs with Douglas-fir.

Boards were dried in a prototype jet dryer (Rosen 1977b) to approximately 12 percent moisture content at the conditions listed in tables 1 and 2. The drying period included one or two drying steps. Boards were periodically removed for 3 minutes from the jet dryer and weighed to the nearest 0.01 pound to establish drying curves for each board. Width and thickness to 0.001 inch were measured at four places along the length of each board before and after drying to determine volumetric

<sup>1</sup>The southern yellow pine was cut from small logs; most of it included the pith and a small amount of heartwood. Douglas-fir contained both sapwood and heartwood.

shrinkage. After drying, all southern pine and several Douglas-fir boards were subjected to a high humidity conditioning period to reduce moisture content gradients and relieve internal stresses in the wood caused by the severe drying conditions. Boards were examined for surface darkening, collapse, honeycomb, and checking. One board from each southern pine run and two boards from each Douglas-fir run were crosscut into several sections to examine internal defects and to obtain 1-inch sections for moisture content determination.

The uncut dried boards were placed in a constant temperature and humidity room until an equilibrium moisture content of 6 percent was reached. Boards were then weighed and moisture contents of the boards during drying were calculated.

## RESULTS AND DISCUSSION

Figure 1 is typical of the moisture-content/time curves for boards dried under constant air velocity and wet bulb temperature. The rate of drying slowly dropped as the drying proceeded. Surface darkening was observed on all boards dried above 212°F. High drying temperatures and low final moisture contents produced the most discoloration: as moisture content dropped below 10 percent, the board surface darkened rapidly at temperatures above 250°F.

### SOUTHERN PINE

Southern pine withstood drying temperatures up to 400°F with minimal degrade. Except for slight end checking and surface checks around knots, the quality of the boards dried at all conditions was good. A previous study with 4/4 silver maple found increases in air velocity above 3,000 fpm did not reduce drying time (Rosen 1977a). But, for southern pine increasing in air velocity reduced drying time (compare the drying times of Runs 2, 3, and 4 in table 1).

Although southern pine can be dried in a few hours at temperatures higher than 300°F,

Figure 1.—Moisture content versus time for 1.75-inch-thick southern pine (Run 2 conditioning period not shown) and Douglas-fir (Run 15) jet dried at 300°F dry bulb, 180°F wet bulb and 3,000 fpm air velocity.

the possibility of overdrying the lumber and the wide range of final moisture contents of the boards are undesirable. The mixed high and moderate temperature schedule of Run 7 (table 1) would reduce the problems involved with a straight high temperature schedule.

### DOUGLAS-FIR

Rapid drying of coastal Douglas-fir is confounded by the wide range of green moisture contents 28 to 146 percent found in the wood. Heartwood boards were drier than sapwood. When drying Douglas-fir at a single high temperature, the heartwood was overdried and the sapwood underdried (fig. 1). Several combinations of high and low temperatures, with and without conditioning steps, were attempted (table 2), but honeycomb and end

checking persisted. Honeycomb was more severe in the boards dried at high temperature only than in those dried at low temperature followed by high temperature (fig. 2). End-coatings did not reduce end checks or honeycomb. Jet drying 1.75-inch-thick Douglas-fir at a constant high temperature is not recommended. A mixed low and high temperature schedule can dry the wood in less than 31 hours, provided some honeycomb of the wood is acceptable.

Figure 2.—Typical honeycomb in Douglas-fir jet dried by a high temperature schedule (A—Run 8) and a low followed by a high temperature schedule (B—Run 11).

## CONCLUSION

Our results indicate that southern pine can be high temperature jet dried in less than 15 hours. The most effective schedule over the range of conditions studied was a short exposure of the wood to very high temperature (above 300°F) followed by a moderately high temperature (220 to 240°F), and finally a high humidity conditioning period. The process could be adapted to a continuous kiln similar to that described by Koch (1977), whereby wood is carried through three sections of a kiln set for the respective conditions stated above. High temperature jet drying of Douglas-fir produced defects in the wood, although drying at low temperature and then increasing to high temperature near the end of drying minimized these defects.

## SPRUCE BUDWORM DEFOLIATION IN MINNESOTA: 1954-1977

Glen Erickson, *Biological Technician,*  
*North Central Forest Experiment Station,*  
*St. Paul, Minnesota*  
and Arthur Hastings, *Entomologist,*  
*Northeastern Area, State & Private Forestry,*  
*Forest Pest Management, St. Paul, Minnesota*

ABSTRACT.— A series of maps showing spruce budworm defoliation in Minnesota, 1954-1977.

OXFORD: 453— 145.718(776). KEY WORDS: Insect outbreaks, maps, history.

The spruce budworm, *Choristoneura fumiferana* (Clemens) is one of the most destructive insect pests of the spruce-fir forests of North America. Between 1910 and 1925 the budworm destroyed 200 million cords of balsam fir and red spruce in the eastern United States and Canada (Metcalf *et al.* 1962). Brown (1970) mapped the spread of spruce budworm outbreaks from 1909 to 1966 in eastern Canada and northern Minnesota. The most recent outbreak in Minnesota (before the present infestation) occurred from 1912 through 1926 (Blais 1968).

This report documents the amount and location of budworm defoliation in northern Minnesota from 1954 through 1977.

The current outbreak was first detected in Minnesota in 1954 along the Canadian border north of

and on the Kabetogama Peninsula east of International Falls. The budworm defoliation increased in area and severity until 1958 when nearly 1 million acres were affected (fig. 1). No formal survey was conducted in 1962. Defoliation continued until 1963 when Ryan and Batzer (1964) reported a decrease in budworm population. As a result of the extended defoliation, up to half (10-50 percent) of the balsam fir died on 112,200 acres and more than half (51-100 percent) died on an additional 130,200 acres.

Because budworm population was low, no extensive surveys were made in 1964 and 1965. However, in 1966 Doerner<sup>1</sup> found heavy defoliation in small areas in the Superior National Forest. Since then, defoliation gradually expanded southward from spruce-fir types along the Canadian border to those in the southern and western portions of the Superior National Forest and adjoining State and private land.

<sup>1</sup>Doerner, Robert G. 1966. *Detection survey of spruce budworm on the Superior National Forest, 1966. Unpublished processed Rep. (File 5220, 2 p).*

Figure 1.—Acres of spruce-fir type defoliated by the spruce budworm in Minnesota, 1954 to 1977.

During the period 1957-1963, about 85,000 Federally owned acres (mostly recreation) were treated with insecticides for budworm control (Fowler 1973).

The following maps are based on aerial and ground surveys conducted by the U.S. Forest Service (North Central Forest Experiment Station, Superior National Forest, and State and Private Forestry), the Minnesota Department of Agriculture (Division of Plant Industry), and Minnesota Department of Natural Resources. They show the yearly progress of budworm defoliation in Minnesota from 1954 through 1977.

LIBRARY

ABSTRACT.—New root and shoot growth of black walnut seedlings were strongly dependent on the amount of time they were kept at a cold temperature. Physiological dormancy ended after approximately 3,100 hours at 3°C, but growth responses continued to increase after 4,600 hours. Root regeneration was strongly correlated with shoot growth.

OXFORD: 181.36:161.9:176.1. KEY WORDS: *Juglans nigra*, cold storage, root regeneration potential.

Absorption of water and nutrients by black walnut (*Juglans nigra* L.) seedlings is primarily a function of new roots (Finn 1966). Slow regeneration of roots may be a possible cause for the slow top growth of walnut seedlings during the first growing season after they are transplanted. Root regeneration potential (RRP), a measure of seedling physiological quality, is the capacity of seedlings to initiate and elongate new roots rapidly after transplanting. High RRP has already been shown to be important to survival and subsequent growth for other species (Stone and Schubert

1959, Stone *et al.* 1962). This paper reports the seasonal pattern of RRP of freshly lifted and stored black walnut seedlings and its relation to chilling.

## METHODS

Eleven liftings of 1-0 black walnut seedlings were made between October 6, 1976, and April 25, 1977, from the Vallonia Forest Nursery, near Brownstown, Indiana. Each lot of seedlings was graded to minimum stem caliper of 0.7 cm, root pruned to 22.0 cm, and then shipped to Carbondale, Illinois. Twelve seedlings were potted at each of the following dates: immediately, December 8, March 10, and May 12. The seedlings that were not potted immediately were stored at 3C until the time they were potted.

Root regeneration potential was determined by a method similar to that of Stone and Schubert (1959). Potted seedlings were placed in a greenhouse for 4 weeks. Air temperature in the greenhouse varied seasonally (minimum 16C), a photoperiod of 16 hours

was maintained by supplemental lighting, and soil temperature was maintained at 24C.<sup>1</sup> At the end of the 4 weeks, the seedlings were unpotted and total shoot elongation, stem caliper 2.5 cm above root collar, oven-dry weight of all new roots, and oven-dry weight of the total root system were determined for each seedling. The length-of-storage-treatments were compared for significant differences by analysis of covariance—total root dry weight was the covariable for root growth response and stem caliper was the covariable for shoot growth response.

## RESULTS AND DISCUSSION

All seedlings had to be subjected to cold temperatures for a minimum amount of time before any appreciable growth response appeared in RRP tests (figs. 1 and 2). During physiological dormancy, seedlings that were potted immediately could not be forced to grow during the 4 weeks in the greenhouse. In late February, an abrupt increase in growth response appeared in the seedlings that were potted immediately (fig. 1). Total shoot elongation and oven-dry weight of new roots steadily increased with successive liftings during the early spring, and continued to increase beyond the time of flushing at the nursery. Seedlings lifted on April 25 had as much as 10 cm of new shoot growth at the time of lifting, but no new root growth. Existing new shoots died back during the RRP test but regrowth of shoots and regeneration of roots surpassed that of all previous lifting dates.<sup>2</sup> Thus, no peak in RRP was found, although it must have been imminent.

The pattern of response in stored seedlings was similar to that for seedlings overwintering in the nursery bed (fig. 2). Seedlings lifted prior to November 1 did not store well. The increase in root growth response was barely evident on March 10 for seedlings lifted on November 1, but an abrupt increase began

<sup>1</sup>Reported to be near optimum by Larson (1970).

<sup>2</sup>Note that this response occurred under favorable greenhouse conditions. In a field transplanting test, seedlings lifted after flushing grew poorly.

Figure 1.—Total shoot elongation and oven-dry weight of new roots for freshly lifted seedlings measured at the end of 4 weeks under forcing conditions in a greenhouse. The plotted values are the covariance-adjusted means of 12 seedlings.

Figure 2.—Total shoot elongation and oven-dry weight of new roots for stored seedlings, measured at the end of 4 weeks after replanting. Seedlings were lifted on November 1 and then replanted on November 1, December 8, March 10, and May 12. Plotted values are the covariance-adjusted means of 12 seedlings.

later in March, which is similar to the response for seedlings that overwintered in the nursery. The pattern of RRP for black walnut seedlings in cold storage is similar to that reported for northern red oak (Farmer 1975), pin oak and scarlet oak (Lee *et al.* 1974), and sugar maple and white ash (Webb 1977).

Seedlings that overwintered outside ended physiological dormancy about two weeks earlier than the stored seedlings, and had consistently more top and root growth in subsequent RRP tests. The winter of 1976-1977 was abnormally cold, so outside seedlings were exposed to many more degree-hours of cold temperatures than stored seedlings. The slower rate of growth resumption of stored seedlings may be due to maintenance of deeper imposed dormancy in storage—the outside seedlings were exposed to warm, sunny weather beginning in late February.

Both ovendry weight of new roots and total shoot elongation were strongly correlated with chilling time,  $r=+0.82$  ( $P\leq 0.05$ ) and  $+0.90$  ( $P\leq 0.01$ ), respectively. Seedlings lifted on November 1 and stored until March 10 had been stored at 3C for 3,100 hours, excluding exposure to cool temperatures in the nursery bed prior to November 1. The longer these seedlings remained in cold storage, the more rapidly they resumed growth and the greater the growth response during the 4-week test period. By May 12, after 4,600 hours at 3C, the peak response had not yet been reached.

In the RRP tests, root growth was strongly correlated with shoot growth ( $r=+0.95$ ,  $P\leq 0.00001$ ); root regeneration increased with the degree of renewed shoot elongation. The major increase in RRP coincided with active shoot growth. However, the data do not depict which process began first.

Root regeneration for seedlings lifted on November 1 and potted on May 12 (198 mg) was lower than that for seedlings lifted and potted on April 25 (249 mg). This suggests that prolonged storage lowered the RRP and/or delayed the peak response.

Overwinter cold storage of fall-lifted black walnut seedlings offers a method of supplying planting stock in physiological condition conducive to resuming rapid growth as early as needed in the spring. Seedlings lifted when

dormant and properly stored can be kept without any apparent detrimental effects at least until mid-May, which is normally beyond the time walnut seedlings are planted in the Central States.

Large, 1-0 black walnut stock, which has been kept under cold conditions a certain length of time and then transferred to favorable growing conditions, has the physiological capability for quickly growing new roots and vigorous new shoots. This study demonstrated that extended cold storage enhanced the rate at which growth of black walnut seedlings was resumed after transfer to environmental conditions favorable for growth. Future research should consider methods to accelerate chilling or enhance the chilling effect so that planting stock with peak RRP is available at planting time.

## SHRUB NESTING OF THE RED-EYED VIREO IN RELATION TO STRUCTURE OF ASPEN FORESTS

William J. Mattson, Jr., *Principal Insect Ecologist*

**ABSTRACT.**— Nests were built in five species of high shrubs in four trembling aspen forests of northern Minnesota. Nest densities ranged between 0.5 and 3.0 per acre and were positively related to the abundance of large (>1.2-cm diameter) shrub stems.

**OXFORD:** 156.1:228.0:148.2 (*Vireo olivaceus*).

**KEY WORDS:** Breeding, nest density, forest structure, nesting habits.

Red-eyed vireos, *Vireo olivaceus* L., (REV) are among the commonest passerine species in the deciduous and mixed deciduous-coniferous forests of northern Minnesota. This note describes their nesting characteristics and nest densities in the shrub layer of four trembling aspen (*Populus tremuloides*) forests in relation to aspects of forest structure.

### METHODS

I selected four study areas, each 25 acres, located in nearly pure stands of trembling aspen (35- to 45-year old) in extreme northern Minnesota, Koochiching County. Each study area was arbitrarily divided into four equal quadrats which were gridded into 64 blocks that were 1/10 acre large. I randomly selected five 1/10-acre plots from each quadrat (20/area) for counting nests which

occurred from ground level to the bottom of the tree canopy (ca. 8 m). For each nest I recorded its height above ground, the species and stem diameter (5 cm above ground) of the shrub in which it was built, the basal area (basal area = cross-sectional area of tree trunks at 137 cm above ground) of overstory trees using a 10-factor prism, and whether the nest was active (with eggs or nestlings) or inactive.

Similar measurements were made on all other nests encountered between 1/10-acre sample plots within each study area but such nests were not used to estimate densities. The study was done between June 15 and 27, 1973, the period when birds were incubating eggs.

### RESULTS AND DISCUSSION Nesting Densities

Nests of the REV occurred in all four study areas (table 1). The number of active nests ranged from 0.0 to 1.0/acre, and the number of inactive nests ranged from 0.5 to 2.5/acre. Inactive nests were in various stages of deterioration because some were built the previous summer. These estimates are in accordance with observations by Southern (1958) and Rice (1978) which show that territory size of males ranges from 0.8 to 1.7 acres, thereby suggesting that nest densities should

range between 0.6 and 1.2/acre if a habitat is fully packed and each male has acquired a mate.

## Nest Locations in Relation to Shrub Species and Height

Nests of the REV occurred in five shrub species: hazel (*Corylus cornuta*), juneberry (*Amelanchier* spp), chokecherry (*Prunus virginiana*), tag alder (*Alnus rugosa*), and mountain maple (*Acer spicatum*) (table 2). These were basically the same species in which Lawrence (1953) found REV nests. In

this study, nest heights ranged from 0.75 to 3.00 m, and averaged 1.55 m over all areas. In other studies where the tree canopy was also included along with shrubs, nest heights were predictably higher: Williamson (1971) (range: 0.6 to 21.4 m, average: 3.2), Southern (1958) (range: 0.4 to 7.9 m, average 2.3), and Lawrence (1953) (range: 1.0 to 16.7 m, average 2.9). In Lawrence's study, 73 percent of the nests occurred at heights less than 4.57 m. All studies reveal, though, that the REV preferentially nests low because in spite of wide ranges in nest heights the mean heights were invariably around 2 to 3 meters.

<sup>1</sup>N or total number of nests observed per area is 13, 21, and 7 for areas 1, 2, and 4, respectively.

<sup>2</sup>Standard error of 0.0 means that n=1.

## Nest Locations in Relation to Overstory

Tree cover around REV nests was usually very dense. For example, mean basal area in the immediate vicinity of individual REV nests averaged 125 feet<sup>2</sup>, although it ranged from 20 to 190 feet<sup>2</sup>/acre. In general, REV nests were located under tree cover that was equal to or denser than the average for the particular study areas. For example, mean basal areas around nests compared with the respective study area means were as follows: 146 vs 125 for area 1; 107 vs 110 for area 2; 140 vs 108 for area 3; and 137 vs 105 for area 4. According to Williamson (1971), the REV characteristically feeds where the canopy is abundant and the understory is moderate to dense. In such environments it has a cylindrical territory extending from the lower understory into the tree canopy.

## Nesting Locations in Relation to Shrub Abundance

REV's apparently select shrubs based on their relative abundances providing all other things are equal. For example, the following tabulation compares the frequency distributions of nests among tall shrubs with frequencies of tall shrubs (>1.2-cm diameter, the smallest stems used by REV's) at area 1 (n = 13 nests) and area 2 (n = 21) where enough nests were found for such a comparison:

### AREA 1

|        |              |               |              |                  |
|--------|--------------|---------------|--------------|------------------|
| Nests: | Alder<br>54% | Cherry<br>23% | Hazel<br>23% | Black ash<br>0%  |
| Shrubs | Alder<br>50% | Cherry<br>0%  | Hazel<br>13% | Black ash<br>37% |

### AREA 2

|         |              |              |              |                 |                      |
|---------|--------------|--------------|--------------|-----------------|----------------------|
| Nests:  | Hazel<br>80% | Alder<br>10% | Cherry<br>5% | Juneberry<br>5% | Misc. Species<br>0%  |
| Shrubs: | Hazel<br>62% | Alder<br>20% | Cherry<br>3% | Juneberry<br>3% | Misc. Species<br>12% |

Frequency distributions of shrubs were determined by counting and measuring all shrubs which occurred on 20 3 m<sup>2</sup> plots randomly placed

within each stand. In spite of differences between frequencies of nests and shrubs, the data still suggest that REV's may distribute their nests in relation to the relative abundances of certain tall shrubs having the proper physical and other attributes. For some reason, REV's apparently avoided black ash at area 1 even though it was abundant and selected chokecherry in spite of its relative scarcity.

Moreover, the density of total nests per acre seems to increase with the density of large shrubs:

|                  |      |      |      |      |
|------------------|------|------|------|------|
| large stems/acre | 5126 | 2360 | 1754 | 1146 |
| total nests/acre | 3.0  | 2.5  | 0.5  | 1.5  |

However, area 3 (1754 stems/acre) was anomalous, having the lowest nest density but not the lowest large shrub density. Since the REV nests across a wide spectrum of heights, it's possible that most REV nested in the canopy rather than in the shrub layer at area 3, thereby accounting for the paucity of nests. This explanation is probable because the tree canopy at area 3 was only 8 to 10 m above the ground, about 3 to 4 m lower than at other areas. In other words, the amount of airspace between the shrub and tree canopies could affect the vertical positioning of nests and the degree of nesting in the shrub layer.

**ABSTRACT.**— Quantifies the effect of spacing on branch diameter, number of branches, and knot surface in a red pine plantation.

**OXFORD:** 245.1:232.43:174.7 *Pinus resinosa*.  
**KEY WORDS:** *Pinus resinosa*, knot surface, poles, piling, branch diameter.

The spatial distribution of trees influences not only main stem diameter growth but also the growth of branches. Wide spacing in plantations results in greater diameter growth at breast height (4.5 feet) than close spacing but the large branches associated with wide spacing reduces tree quality. Close spacing results in smaller branches, but more of the branches die due to shading and produce loose knots. The purpose of this note is to quantify the effect of spacing on number of branches and branch diameter, both of which influence one tree quality characteristic — knot surface.

### METHODS

The study area, located in Burnett County in northwestern Wisconsin, was planted in the spring of 1958 with 2-1 red pine (*Pinus resinosa* Ait.) nursery stock on soil described as Plainfield

sand.<sup>1</sup> Seedlings were planted at spacings of 5- by 5-, 7- by 7-, 9- by 9-, and 11- by 11-feet. Site index is estimated at 70 feet. Mean height of dominant and codominant trees is 32 feet, and mean stand diameters for the four spacings are 4.3, 5.5, 6.5, and 7.3 inches, respectively. Total tree age is 23 years.

Six trees from each of the four spacings were sampled. Only dominant or codominant trees were selected because they represent potential crop trees. Diameter of all branches greater than 0.10 inch was measured in each whorl up to and including the third whorl below the terminal bud. Measurements were made 1.0 inch from the tree bole.

## RESULTS

### Branch Diameters

The 5- by 5- and 11- by 11-foot spacings are significantly<sup>2</sup> different in mean branch diameter from each other and the other spacings. Comparisons between the 7- by 7- and 9- by 9-foot spacings

<sup>1</sup>Study maintained in cooperation with Burnett County and Wisconsin Department of Natural Resources.

<sup>2</sup>All statistical tests of significance were made at the 5 percent level.

showed barely nonsignificant differences, and except for one or two whorls, the 9- by 9-foot spacing consistently had larger diameter branches than the 7- by 7-foot spacing (table 1).

Branch diameter increased with height above ground to 3 feet for the 5 by 5 spacing and to 8 feet for the 11 by 11 spacing and remained constant to 17 feet for the 11 by 11 spacing and 24 feet for the 5 by 5 spacing. The other spacings were intermediate between these. Stielt (1964) observed this same relation. Wambach (1967) hypothesized this relation as total tree height increases faster than height to live crown at young ages. Thus, up to a certain age, each successive whorl lives slightly longer than the whorl below it. For this study, these ages are 5, 6, 7, and 8 years from planting for the 5- by 5-, 7- by 7-, 9- by 9-, and 11- by 11-foot spacings, respectively.

The top whorl measured in this study was 3 years old. Within the last 5-year history of this stand, branch diameter growth decreased markedly for branches 4 years old regardless of spacing. Branch diameter growth virtually ceases at branch ages 5 to 7 years, progressing from the 5- by 5- to 11- by 11-foot spacings. Therefore, branch size in plantations 15 to 20 years old may be a good indication of branch size for red pine until the first thinning.

## Number of Branches

Number of branches per whorl did not differ significantly between the four spacings (table 1). Similar results were observed by Stielt (1964) and Wambach (1967). Whorls above 3 feet averaged 6 branches per whorl (due to natural pruning, fewer branches remained below 3 feet). The number of branches was uniform from whorl to whorl — probability of having < 5 or > 7 branches is 0.07 and 0.14, respectively, and probability of having < 4 or > 8 is only < 0.03.

## Knot Surface

Knot surface is defined as the sum of branch diameters and is a recognized standard of unsuitability for poles and piling. Eight inches of knot surface in any linear foot for branches greater than 0.49 inch is a common upper limit for product acceptance (Panshin *et al.* 1950). Trees in the 9- by 9- and 11- by 11-foot spacings either have exceeded or are rapidly approaching this 8-inch knot surface limit (table 1). This is particularly critical in the live crown because these branches will continue to grow after the first thinning.

The trees in this study have not attained the minimum top diameter and length for building poles, utility poles, natural taper piling, or standard piling. Currently, thinnings would yield

<sup>1</sup>2-1 trees planted; total tree age is 23 years.

<sup>2</sup>Measured 1 inch from bole.

pulpwood and posts, and knot surface is not a recognized standard of unsuitability for these products. Thinnings in 10 years will yield building poles, in 20 years will yield small utility poles plus a few natural taper piling, and in 30 years will yield some standard piling.

## DISCUSSION

It is evident from this study, and implied by Stiell (1964) and Wambach (1967), that even at close spacings red pine retain most dead branches up to 20 years. Arend (1955) noted persistent dead branches to the ground in closely spaced red pine after 40 years. Thus, to produce an abundance of clear wood on rotations less than 100 years, pruning will be necessary regardless of spacing.

One advantage of wide spacing is to shorten the time to the first commercial thinning. However, this will necessitate pruning before the first thinning to minimize the size of the stem's "knotty" core and increase tree quality by allowing knots to be overgrown with strong clear wood. Crop trees in the 9- by 9-foot and wider spacings should be

pruned before the first thinning, whereas pruning of crop trees in spacings closer than 9 by 9 feet could be delayed until the first thinning.

In the absence of pruning, plantation spacings 11 by 11 feet and wider would sharply curtail or eliminate the production of poles and piling.

PULPWOOD PRODUCTION IN THE LAKE STATES, BY COUNTY, 1978

James E. Blyth, *Principal Market Analyst*,  
 and W. Brad Smith, *Associate Mensurationist*

ABSTRACT.-- Pulpwood production in the Lake States--Michigan, Minnesota, and Wisconsin--advanced from 4.74 million cords in 1977 to 4.91 million cords in 1978. Pulpwood production is shown by county and species group for these three States.

OXFORD: 861.0(77):792. KEY WORDS: Residue, Michigan, Minnesota, Wisconsin.

Lake States pulpwood production inched up to 4.91 million cords in 1978 from 4.74 million cords in 1977. By State, production was 1.89 million cords in Wisconsin (up 4 percent), 1.68 million cord in Michigan (up 5 percent), and 1.34 million cords in Minnesota (up 0.4 percent).

Nine out of 10 cords came from roundwood (including chips); the other cord came from mill residue such as slabs, edgings, veneer cores, and chips from those materials. Production from softwood and hardwood residue by State was:

| <u>State</u> | <u>Softwood</u><br>(Hundred standard cords) | <u>Hardwood</u><br>(Hundred standard cords) |
|--------------|---|---|
| Michigan     | 268   | 1,203                                       |
| Minnesota    | 353   | 744   |
| Wisconsin    | 404   | 1,835                                       |

Pine pulpwood output climbed to a record 820,000 cords, 88,000 cords ahead of 1977. Other moderate increases were in maple (77,000 cords), aspen (34,000 cords), and birch (24,000 cords). Elm pulpwood production fell 34,000 cords; several other species had nominal declines.

Harvesting rose substantially in the Western Upper Peninsula and Northern Lower Peninsula of Michigan and in Northwestern Wisconsin. No area had a significant harvest reduction.

Counties producing more than 100,000 cords were Iron, Marquette, and Dickinson in Michigan; St. Louis, Koochiching, and Itasca in Minnesota; and Oneida, Price, Marinette, and Forest in Wisconsin (table 1).

Pulpmills using Lake States timber in 1978 reported their pulpwood receipts by species group and State and county of origin. Their cooperation is gratefully acknowledged. Thanks are also due the Michigan Department of Natural Resources for collecting the data from pulpmills in Michigan.

### MATERIALS AND METHODS

**ABSTRACT.**— Five hybrid poplar clones were presented to 16 penned white-tailed deer on a feeding board over a 3-day period in September, 1978. A definite order of preference was observed over a 3-hour period for each of 3 trials. Over a longer period (8-24 hours), all 5 clones were completely consumed.

**OXFORD:** 151.3—149.6 **CER. KEY WORDS:** browse, intensive culture, plantations.

Knowing how palatable hybrid poplar clones are to white-tailed deer (*Odocoileus virginianus*) is important if plantations of these clones are to be established. Certain genotypes may be preferred over others even though gross physical characteristics are very similar<sup>1</sup>. The objective of this study was to determine feeding preference by white-tailed deer for various hybrid poplar clones that are being used in intensive culture studies at the Forestry Sciences Laboratory in Rhinelander, Wisconsin.

Five hybrid poplar clones were presented to 16 penned white-tailed deer on a feeding board over a 3-day period in September 1978.

Leafy twigs of the 5 clones were harvested from experimental plots at the Forestry Sciences Laboratory on September 12, 1978 (table 1). The twigs were placed in plastic bags, packed with crushed ice in styrofoam containers and delivered for testing to Ashland, Wisconsin. All the vegetation, even that used 3 days after delivery, appeared to be in good condition. The careful packing preserved the color and turgor of the leaves.

In preparation for the feeding trials, each twig was trimmed to 12 inches with 10 leaves left on each twig. In each feeding trial, 10 twigs of each clone were tied together in a bundle and secured to a feeding board 10 feet long and 4 inches wide. The feeding board was attached to 2 trees so that the tops of the clone bundles were 4 feet from the ground. Clonal order on the board was randomized.

The number of leaves in each bundle was counted at half-hour intervals for 3 hours, and again after the material had been in the deer yard at least 8 hours. Three separate feeding trials were run.

Table 1.—*Parentage of clones used in September, 1978 penned deer studies*

| Clone number | Clone and/or parentage                         | Received from— and number |
|--------------|--|---------------------------|
| 5260         | P. 'Tristis #1', (P. tristis × P. balsamifera) | Indian-Head, Sask.        |
| 5262         | P. cv. Candicans × P. cv. Berolinensis         | Upper Darby, PA. NE-385   |
| 5272         | P. nigra × P. laurifolia                       | Upper Darby, PA. NE-1     |
| 5325         | P. × euramericana cv. Ostia                    | Maple, Ontario DN-28      |
| 5332         | P. cv. Betulifolia × P. trichocarpa            | Upper Darby, PA. NE-98    |

The penned deer are normally fed by park personnel in the early afternoon. Food consists primarily of hay and grain. In addition, residents of the area often visit the deer yard and bring bread, apples and other foods.

## RESULTS AND DISCUSSION

The time of presenting the clones to the animals influenced how quickly the vegetation was consumed. The deer appeared most interested in the poplars when hay and grain were not available. However, time of presentation had no apparent effect on clonal preference.

In trial #1 (table 2), the deer had not been fed by park personnel for almost 24 hours, but evidence of

other feeding was prominent. The clones were immediately investigated by several animals and some browsing took place on all five clones. Three animals (two does and a buck) browsed on clones 5325 and 5272. They repeatedly wandered away but returned each time to the same two clones. The remaining animals (13) showed little interest in the material after their initial examination.

The other two trials showed that the same clones were preferred but the time required to consume all leaves was different (table 3). Over a longer period (8-24 hours) the leaves from all 5 clones were completely consumed. In some instances even the twigs were eaten. In trial #3 all 16 animals actively investigated and browsed on the clonal material.

Table 3.—*Clonal preference based on three feeding trials with penned deer*

| Clone number | Trial 1 | Trial 2 | Trial 3 |
|--------------|---------|---------|---------|
| 5325         | 1       | 1       | 1       |
| 5272         | 2       | 2       | 2       |
| 5332         | 3       | 3       | 3       |
| 5260         | 4       | 4       | 5       |
| 5262         | 5       | 5       | 4       |

Care must be taken in interpreting the results of this study since the natural browse in the 5-acre deer yard has long been depleted. It is possible that browse material consumed in this study might be ignored in the field.

Table 2.—*Leaves remaining after various periods of elapsed time in deer pen*

# SOIL STRUCTURE AND MYCORRHIZAE ENCOURAGE BLACK WALNUT GROWTH ON OLD FIELDS

Felix Ponder, Jr., *Research Soil Scientist,  
Carbondale, Illinois*

**ABSTRACT.**—Examination of black walnut seedlings grown in forest and field soils showed all root systems were infected with mycorrhizae; the amount of infection was influenced by treatments. Mean height and dry weight of tops and roots were greater for seedlings grown in forest than field soil. Seedling height growth was not increased by disturbing either soil; but, root dry weight was significantly increased by disturbing the field soil.

OXFORD: 114.14:181.351:176.1 *Juglans nigra*.  
KEY WORDS: Endomycorrhizal fungi, bulk density sampling, soil sterilization.

Black walnut trees (*Juglans nigra* L.) planted on abandoned fields often grow much less than trees planted on cleared forest sites or on old fields reverted to tree cover (Carmean *et al.* 1976). Good soil structure, valuable for promoting plant growth and microorganisms, is less common in old fields than in the undisturbed soils under continuous forest cover.

Black walnut is known to form vesicular-arbuscular (VA) mycorrhizae. Mazur and Semahanova (1965) reported that mycorrhizae developed best on *J. regia* L. at 40 to 50 percent moisture content, and seedling development (foliation, height, stem diameter, and root system) was positively related to the amount of mycorrhizae formation.

This report describes the influence of disturbed and undisturbed soils from both forested and abandoned field sites, and the effects of inoculation with VA endomycorrhizal fungi on the growth of black walnut seedlings under greenhouse conditions.

## METHODS

In the spring of 1978, soils of the Wellston series (fine-silty, mixed, mesic-Ultic Hapludalfs) were collected from a forest and an abandoned field on the Kaskaskia Experimental Forest in Hardin County, Illinois. This silt loam soil is well-drained and was formed in loess and underlying material weathered from sandstone or shale bedrock. Topsoil thickness averaged 12 cm in the forest and 8 cm in the abandoned field. Subsoil thickness averaged nearly 1 m to sandstone bedrock in both soils. The abandoned field (last cultivated in early 1960's) was dominated with broomsedge (*Andropogon virginicus* L.), and had been sparsely invaded by white ash (*Fraxinus americana* L.), green ash (*F. pennsylvanica* var. *subintegerrima* (Vahl.) Fern.), yellow-poplar (*Liriodendron tulipifera* L.), sassafras (*Sassafras albidum* Nutt.), and flowering dogwood (*Cornus florida* L.). The forest area is adjacent to the field and has sawtimber-size white oak (*Quercus alba* L.), white ash, yellow-poplar, and several large diameter black walnut (*Juglans nigra* L.) trees.

Using a newly designed soil sampler and cast acrylic resin tubes, relatively undisturbed soil cores 20 cm in diameter were obtained from the upper 36 cm of both forest and field. Sections of burlap were fastened over the bottom ends of the tubes to retain soil. Soils for the disturbed treatment were also collected from the upper 36 cm of the forest and field. This soil was thoroughly disturbed by the use of a mechanical shredder and equal amounts (by weight) were put into epoxy painted (inside and outside) galvanized steel containers the same size as the acrylic containers and secured with burlap.

Sixty containers each of the forest and field soils were prepared. Treatments included undisturbed (U), disturbed (D) undisturbed autoclaved (UA), disturbed autoclaved (DA), undisturbed, autoclaved, and inoculated (UAI), and disturbed, autoclaved, and inoculated (DAI). Each treatment was replicated 10 times for each of the two soils. All containers were randomly placed in a shaded greenhouse in mid-May 1978. The acrylic containers were covered with aluminum foil to prevent roots from being affected by sunlight.

Autoclaved soils were treated at 122C and pressure of 1.5 kg/cm<sup>2</sup> in containers for two 2-hour periods separated by 24 hours. Autoclaved and inoculated soils were inoculated by forcing a 10 mm sterilized glass tube into the soil to a depth of 10 cm in each container at three equi-distant locations, removing a plug of soil, and inserting a sterilized glass tube of nonautoclaved forest soil into the hole. An additional 10 g of nonautoclaved forest soil was broadcast over the surface to complete inoculation.

One pregerminated black walnut seed that had been surface-sterilized with sodium hypochlorite was planted in each container. Seedlings were watered with distilled water as needed throughout the growth period.

After 12 weeks of growth, seedlings were harvested and stem height and diameter (2.54 cm above root collar) were recorded. Roots were separated from tops and rinsed thoroughly in tap water. Six 10-cm lengths per treatment were randomly removed and examined microscopically at 100X for the presence of VA mycorrhizal infection after clearing and staining according to the method of Phillips and Hayman (1970). The root was scored mycorrhizal if hyphae, arbuscules, or vesicles were present separately or together in

any part of the root segment. The density of the infection was not measured. The remaining roots and tops were oven-dried for 24 hours at 65C and weighed.

## RESULTS AND DISCUSSION

### Mycorrhizae

Roots of seedlings grown in all treatments of the undisturbed and disturbed forested and field soils were mycorrhizal, but the amount of infection was influenced by treatments (figs. 1D and H). Autoclaving undisturbed forest soil cores (UA) reduced mycorrhizal infection to 40 percent, but autoclaving undisturbed field soil cores reduced mycorrhizal infection only to 80 percent. When undisturbed and autoclaved forest soil cores (UA) were inoculated (UAI) the mycorrhizal infection increased from 40 to 60 percent and in the case of the field soil (UAI), roots were 100 percent infected as were seedlings in the undisturbed field cores. Thus, it can be concluded that autoclaving undisturbed soils at 122C reduces mycorrhizal infection but does not completely eliminate infection.

Results were similar for seedlings grown in disturbed and autoclaved cores for both forest and field soils (fig. 1D and H). Autoclaving disturbed forest and field soils (DA) reduced mycorrhizal infection much more than autoclaving undisturbed soils (UA), and when these disturbed and autoclaved soils were inoculated (DAI) mycorrhizal infection was greatly improved. The percent infection increased from 20 to 100 in roots of seedlings grown in field soil cores but only from 20 to 60 for seedlings in forest soil cores. Thus, it can be concluded that inoculation of both forest and field soils that have been autoclaved improved mycorrhizal infection. Also, the inoculum and the method used for inoculation, although improving infection, did not usually result in the 100 percent infection observed in soils that were not autoclaved.

### Seedling growth

Comparison of mean height and dry weight of roots and tops shows that seedlings grown in containers of forest soil were superior to those in the field soil (fig. 1A,B,C,E,F,G). Much of the greater height, and top and root dry weights of

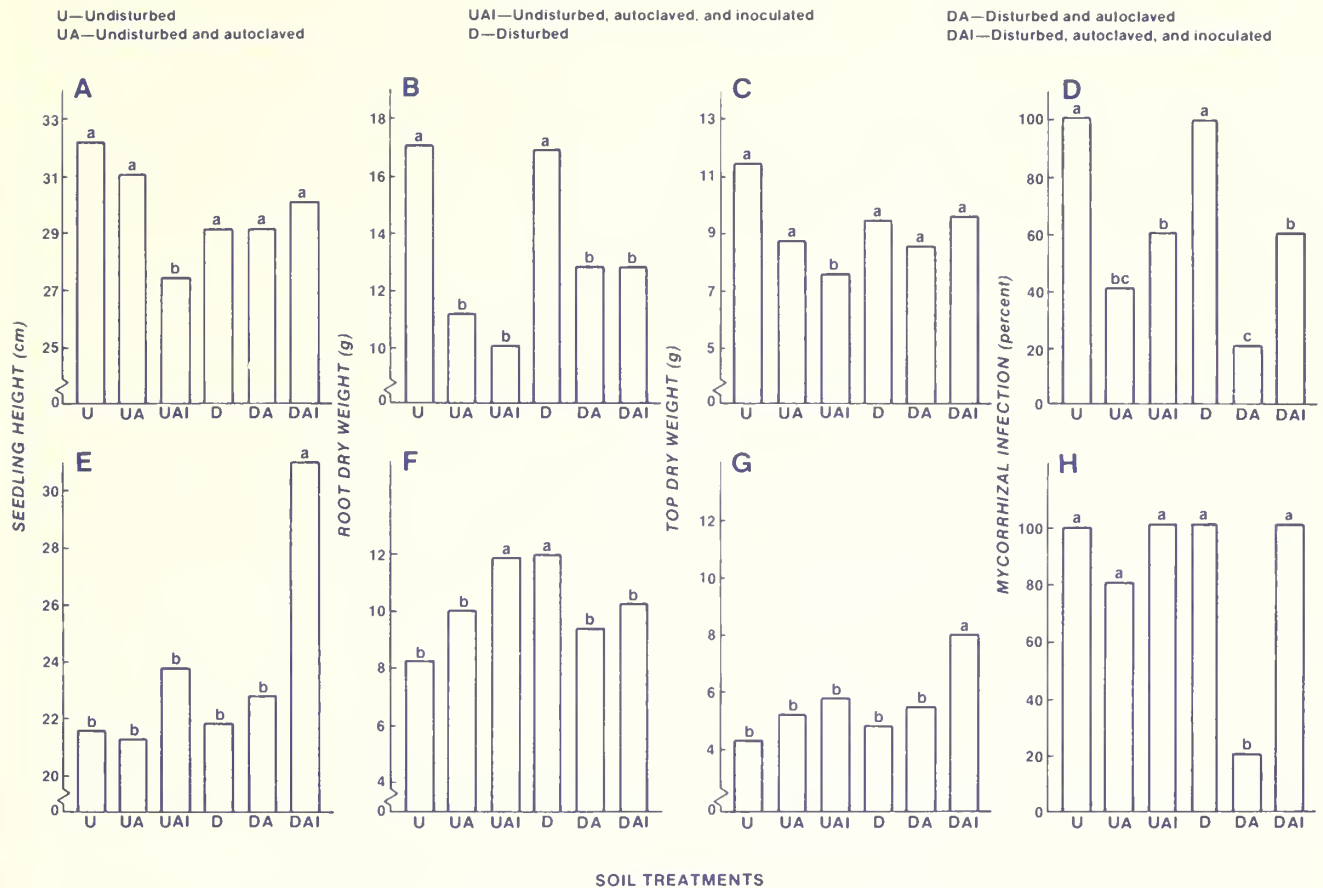

Figure 1.—Effects of soil treatments on seedling height, root dry weight, top dry weight, and mycorrhizal infection in forest soils, A through D respectively; and field soils, E through H respectively. (Bars with the same letters are not significantly different at the 0.05 level. Means of 10 plants.)

seedlings grown in forest soil may be attributed to its lower bulk density, and greater nutrient and organic matter content compared to field soil (table 1). Height growth of seedlings was not increased by disturbing the forest soil (D). Clark (1964) showed that yellow-poplar seedlings grown in undisturbed forest soil had greater height and dry weight than seedlings grown in disturbed forest soil.

The root dry weight of seedlings grown in disturbed field soil was significantly increased over seedlings grown in undisturbed field soil. Undisturbed field soils are dense (1.40 g/cm<sup>3</sup>, table 1); disturbing these soils reduced bulk density to 1.18 g/cm<sup>3</sup>. Thorough loosening of the soil may not always be desirable, as some plants require rather dense soil for best root-soil contact and growth. Evidently loosening the field soil in this

study improved soil aeration and favored root penetration, proliferation, and growth. An increase in root mass in response to lowering the soil bulk density might lead to improved top growth differences in old field plantings years later.

Lack of mycorrhizae is likely not a problem in the growth of black walnut on abandoned field sites. However, the more dense, and less aerated condition of undisturbed field soils might have diminished VA mycorrhizal activity and thus reduced the ability of seedlings to absorb nutrients and moisture. We did not determine whether the mycorrhizae in forest and field soils are the same organisms. If they are different and some are more effective in promoting growth than others, infection alone may not mean much (Marx *et al.* 1971).

Both broomsedge and sassafras in the abandoned field vegetation contain allelopathic compounds that have been known to inhibit the growth of several competing plant species (Rice 1972); others inhibit nitrogen fixing and nitrifying bacteria (Rice 1964, Gant and Clebsch 1975). Carmean *et al.* (1976) suggested that allelopathic compounds produced by broomsedge and sassafras may reduce the growth of planted hardwoods. In most cases reduced plant growth has been attributed to low soil nitrogen. There may be a connection between low soil nitrogen and allelopathy that is not yet completely understood (Rice 1977).

## CONCLUSION

Black walnut seedlings grown in both forest and field soils were mycorrhizal to some degree. Forest soil had the best growth of all treatments, and seedlings were well infected with endomycorrhizae. Good seedling growth is apparently dependent on high mycorrhizal infection rates—rates that could not be achieved by autoclaving and then inoculating previously undisturbed forest soil. Disturbing field soils reduced bulk density and increased average root dry weight of seedlings. Even though establishment of mycorrhizal infection is no problem in old fields, soil structure may restrict optimal mycorrhizal development. We conclude that both mycorrhizae and

soil structure are important in black walnut seedling growth.

Felix Ponder, Jr., Soil Scientist,  
Carbondale, Illinois

**ABSTRACT.**— Rabbit droppings and grasshoppers were collected on recently graded coal mine spoil to determine if they were vectors of endomycorrhizal fungi. After 6 weeks of growth, roots of rye grass and sudan grass grown in mixtures of sterilized sand containing either unsterilized rabbit droppings or grasshoppers were endomycorrhizal, while the roots of plants grown in sterilized mixtures of these were not.

**KEY WORDS:** Mycorrhizae, spoil banks, animal vectors, revegetation, insect vectors.

Coal strip mine operations alter the natural soil strata, producing a mixture of rock fragments, clays, coal fragments, and the original soil. The site condition of this heterogeneous mixture is varied, and commonly referred to as "spoil".

Microflora investigations of plants growing on spoils have shown plants to be infected with vesicular arbuscular (VA) endomycorrhizae. Daft *et al.* (1975) found endomycorrhizae on roots of grasses and other herbaceous plants colonizing anthracite and bituminous coal spoils in Pennsylvania and bituminous coal spoils in Scotland. Marx (1975) reported that grasses, trees, and herbaceous plants on both artificially and naturally revegetated coal spoils in Kentucky and Virginia were endomycorrhizal infected to some degree. Endomycorrhizal fungi are thought to spread slowly— mainly by water, soil movement, and possibly mammals and insects. Recently, Trappe and Maser (1976) found spores of *Glomus macrocarpus* Tul. & Tul. to be viable after passing through the

digestive tract of rodents. The purpose of the present study was to determine if the mammals or insects that frequented a recently graded spoil could be vectors of endomycorrhizal fungi.

## METHODS

In mid-summer 1978, rabbit droppings and live grasshoppers were randomly collected at the Sahara Coal Mine Company near Carrier Mills, Illinois on a spoil graded in the fall of 1977. (According to the 1971 Illinois Surface-Mined Land Conservation and Reclamation Act, top soil need not be replaced.) The rabbit droppings and grasshoppers were divided into two portions. One portion, along with several containers of builders sand, was sterilized by autoclaving at 122C and 17 psi for two 2-hour periods; the second period was 24 hours after the first. The second portion of the droppings and grasshoppers were dried for 72 hours at 30C in an oven, crushed and mixed separately with autoclaved sand in separate lots. Similarly sterilized rabbit droppings and grasshoppers were crushed and mixed with sterilized sand. Four replications each of rye grass (*Lolium perenne* L.) and sudan grass (*Sorghum sudanense*) were planted in 1-gallon containers with the mixtures. Both a sterilized and unsterilized sand control were also planted. All plants were grown for 6 weeks under greenhouse conditions.

Plant roots were examined for VA endomycorrhizal presence with a compound microscope at 100X

after clearing and staining the roots according to the method of Phillips and Hayman (1970).

## RESULTS AND DISCUSSION

Careful examination of plants growing in sterilized sand mixed with either unsterilized rabbit droppings or grasshoppers showed some of them to be endomycorrhizal. As shown in the following tabulation, after 6 weeks of growth, plants were 20 and 31 percent infected when grown in sterilized sand containing unsterilized rabbit droppings, and in sterilized sand and grasshoppers, respectively. Plants grown in sterilized sand containing either sterilized rabbit droppings or sterilized grasshoppers had no infection.

| Treatment                                       | Rye grass            | Sudan grass |
|---|----------------------|-------------|
|   | Percent <sup>1</sup> |             |
| Unsterilized sand                               | 7                    | 8           |
| Sterilized sand                                 | 0                    | 0           |
| Sterilized sand + sterilized rabbit droppings   | 0                    | 0           |
| Sterilized sand + unsterilized rabbit droppings | 20                   | 28          |
| Sterilized sand + sterilized grasshoppers       | 0                    | 0           |
| Sterilized sand + grasshoppers                  | 22                   | 31          |

Gerdemann and Trappe (1974) found mature *Endogone* spores that had passed through the digestive tracts of mammals without morphological changes. However, no viability tests were done on spores. Taylor, Vorhies, and Lister (1935) state that jack rabbits (*Lepus californicus melanotis*) regularly defecate as they feed, or very soon afterwards. Therefore, it is probable that many fungal propagules could pass through a rabbit's digestive tract unharmed.

Hansen and Ueckert (1970) reported ingestion of fungi by crickets and grasshoppers. According to Gerdemann and Trappe (1974), some of this fungal material was later identified as spores of Endogonaceae.

Although droppings of rodents were not investigated in this study as a means of endomycorrhizal dispersal, rodents such as field mice are known to feed upon a variety of endomycorrhizal fungi (Bakerspigel 1958). Near the study area, 33 mice were trapped in one night using the line transect method (Dennis Harmon, personal communication).

Fumigated nursery soil and other areas treated to preclude micro-organisms may be reinfected by rabbits and grasshoppers or other vectors that feed or

come in contact with such fungi. South (1977) states that both inoculated and uninoculated soil that had previously been fumigated with methyl bromide produce seedlings having the same amount of infection.

## SUMMARY AND CONCLUSION

Rabbit droppings and live grasshoppers were collected from a recently graded coal mine spoil. A portion of both along with builders sand was sterilized while the remaining portion was not. These were mixed separately with sterilized sand and planted with rye grass and sudan grass. After 6 weeks, a number of roots growing in both the unsterilized rabbit droppings and grasshoppers and sterilized sand mixtures were endomycorrhizal, while the roots of plants in either mixture containing sterilized rabbit droppings and sterilized grasshoppers and sterilized sand were not. Results from this study show that both rabbits and grasshoppers are vectors of endomycorrhizal fungi. Further research is needed to determine how important small mammals and insects such as rabbits and grasshoppers are in the dispersal of endomycorrhizae.

LIBRARY

**ABSTRACT.**—Shows stocking density has little effect on wood specific gravity of red pine.

**KEY WORDS:** *Pinus resinosa*, wood quality, wood strength.

Red pine (*Pinus resinosa* Ait.) covers more than one million acres in Michigan, Minnesota, and Wisconsin. A large percentage of this acreage is plantations. Early thinnings of these plantations will yield pulpwood, posts, and some poles. And, specific gravity of this wood is an important quality factor affecting fiber yield, working and finishing qualities, and strength. The purpose of this note is to quantify the effect of spacing on wood specific gravity for red pine grown on a good site.

### METHODS

The study area, located in Burnett County in northwestern Wisconsin, was planted in the spring of 1958 with 2-1 red pine nursery stock on soil described as Plainfield sand.<sup>1</sup> Seedlings were planted at spacings of 5- by 5-feet, 7- by 7-feet, 9- by 9-feet, and 11- by

<sup>1</sup>Study maintained in cooperation with Burnett County and Wisconsin Department of Natural Resources.

11-feet. Mean height of dominant and codominant trees is 32 feet, and mean stand diameters for the four spacings are 4.3, 5.5, 6.5, and 7.3 inches, respectively. Total tree age is 23 years. Site index is estimated at 70 feet.

Six trees from each of the four spacings were sampled. Only dominant and codominant trees were selected because they represent the effect of spacing on specific gravity without the additional effect of suppression on specific gravity that would be present in intermediate and suppressed trees. A disc was cut at 4.5 feet and between each whorl from the base of the tree up to and including the current year's growth. The bark was removed and the green discs soaked in water for 48 hours, weighed to the nearest 0.5 gram, and immersed and weighed again to determine volume by the displacement method. Discs were oven-dried (70C) for 48 hours and weighed a third time. Specific gravity was determined by:

$$\text{Specific gravity} = \frac{\text{ovendry weight}}{\text{weight (wet, air)} - \text{weight (wet, immersed)}}$$

### RESULTS

Specific gravity at 4.5 feet increased as the number of trees per acre increased (table 1). However, the

Table 1.—*Specific gravity of dominant trees in a 20-year-old plantation*<sup>1</sup>

<sup>1</sup>2-1 trees planted, total tree age is 23 years.

only difference of any magnitude occurred between the trees in the 5- by 5-foot spacing and those in the other three spacings. The same relation was exhibited at other heights above ground (table 1).

In a similar study, Wambach<sup>2</sup> (1967) investigated the relation between specific gravity and spacing in red pine plantations over a wide range of sites. He determined specific gravity from increment cores taken at 4.5 feet and produced an equation to predict specific gravity as a function of site index and number of trees per acre. Our estimate of specific gravity for 889 (7- by 7-foot), 538 (9- by 9-foot), and 360 (11- by 11-foot) trees per acre are close to his estimates (+ 1.3 to 1.8 percent). However, our estimate of specific gravity for 1,742 (5-by 5-foot) trees per acre deviates from his by +4.6 percent and equals his estimate of specific gravity for 1,600 trees per acre at site index 57.

We hypothesize that on good sites with narrow spacing, competition occurs early and diameter growth parallels that of plantations with fewer trees

per acre but on poorer sites. If this is true, the mean stand diameter of 1,600 trees per acre, site index 57, should be approximately the same as our mean stand diameter. Because there is a 1- or 2-year difference in reaching 4.5 feet in height, the number of growth rings at 4.5 feet for 25-year-old trees, site index 57, should not differ by more than one from 23-year-old trees, site index 70. From Wambach,<sup>2</sup> the mean stand diameter for 25-year-old trees, site index 57, with 1,600 trees per acre is 4.3 inches, the same as our plantation with 1,742 trees per acre.

The combination of age, site index, and 5- by 5-foot spacing of our plantation is on the periphery of the 85 plantations in Wambach's data set. And, perhaps, his data set could not capture this trend. Although our estimate of specific gravity for very narrow spacing and good site differs from Wambach's, for practical purposes it is probably unimportant because this combination of site index and spacing represents a small percentage of existing plantations.

## DISCUSSION

The spatial distribution of trees has a large effect on main stem diameter growth<sup>2</sup> and size of branches<sup>3</sup> but has little effect on the specific gravity of wood. Spacing of trees from 7 to 11 feet did not change specific gravity more than 2 percent and the closest spacing of 5 feet increased specific gravity about 5 percent. The use of narrow spacing in red pine plantations is not a practical method to increase specific gravity, and little concern should be given to small decreases in specific gravity of red pine at very wide spacings.

## FULL-TREE SKIDDING FAVORS BLACK SPRUCE REPRODUCTION UNDER CERTAIN PEATLAND CONDITIONS

William F. Johnston, *Principal Silviculturist,*  
*Grand Rapids, Minnesota*

LIBRARY

**ABSTRACT.**—Two trials on different sites indicate that clearcut black spruce reproduces well after full-tree skidding only on nonbrushy sites that have fairly abundant sphagnum seedbeds and adequate natural seeding.

**OXFORD:** 231.3:375.4:174.7(776) *Picea mariana*.  
**KEY WORDS:** *Picea mariana*, mechanized harvesting, site preparation, natural seeding, broadcast burning, Minnesota.

Because of increased mechanization, full-tree skidding has become a popular way to harvest black spruce (*Picea mariana* (Mill.) B. S. P.) on the extensive peatlands of north-central Minnesota. However, compared with broadcast burning, little is known about full-tree skidding as a method of site preparation for reproducing clearcut black spruce by natural seeding. Findings have been reported for only one trial 2 years after skidding (Johnston 1975), plus two other studies where piling of slash simulated full-tree skidding by keeping seedbeds exposed (Johnston 1971, Verry and Elling 1978). Further, this research was done only on **nonbrushy** sites that had **abundant** sphagnum moss (*Sphagnum* spp.)—a good seedbed. So even though actual or simulated skidding resulted in satisfactory reproduction under these conditions, no findings have been reported to guide forest managers dealing with other conditions.

However, 2-year results are now available from a trial of full-tree skidding on a **brushy** site that had **sparse** sphagnum seedbeds. And 7-year results are

available from the previous skidding trial mentioned above. The overall results from these two trials indicate that at present full-tree skidding is reliable for reproducing black spruce only on nonbrushy sites that have fairly abundant sphagnum seedbeds and adequate natural seeding.

### PROCEDURE

The trials were made in mature stands of black spruce on separate peatlands near Big Falls in north-central Minnesota.<sup>1</sup> The **brushy** site, which apparently receives nutrient-enriched soil water from an adjacent upland, represents good site quality for black spruce growing on organic soil. The stand was low density (at least partly because of wind-caused mortality), had trees such as balsam fir (*Abies balsamea* (L.) Mill.) and paper birch (*Betula papyrifera* Marsh.), tall shrubs such as speckled alder (*Alnus rugosa* (Du Roi) Spreng.), and sparse sphagnum seedbeds. The **nonbrushy** site, which represents medium site quality, had a dense stand of pure black spruce, no tall shrubs, and abundant sphagnum seedbeds.

Harvesting was done in winter when the ground was frozen. The brushy site was harvested the same way as the nonbrushy site (Johnston 1975): trees 2

<sup>1</sup>The cooperation of the Minnesota Department of Natural Resources, Division of Forestry, is gratefully acknowledged.

inches d.b.h. and larger were felled; those 3 inches d.b.h. and larger were pulled to a landing as whole trees by a rubber-tired skidder, and then processed. Felling and skidding were done with reasonable care to minimize breaking off branches and tops. The harvest averaged 16 and 26 cords of conifer pulpwood per acre on the brushy site and nonbrushy site, respectively.

Natural seeding was provided by a mature stand of black spruce that bordered the brushy site (230 by 730 feet) on the long, windward side and the nonbrushy site (330 by 530 feet) on three sides. Although the brushy site's seed source averaged only 40 square feet of basal area per acre for spruce trees more than 3.5 inches d.b.h., seeding was considered adequate because a similar site nearby with a similar seed source reproduced satisfactorily after broadcast burning. The brushy site was sampled the same way as the nonbrushy site (Johnston 1975): tree reproduction was counted on a 1/4-milacre subplot in 100 well-distributed milacre plots 2 years after skidding; if black spruce was absent on the subplot, its presence was checked on the whole plot to determine milacre stocking. Also, seedbeds were recorded by cover class on the 100 1/4-milacre subplots to help explain reproduction results.

The nonbrushy site, which continued to receive natural seeding, was resampled 7 years after skidding to find out if the reproduction had changed substantially since 2 years after skidding. Data were obtained from the previously established 100 subplots and plots as described above. In addition, the height of the tallest black spruce and quaking aspen (*Populus tremuloides* Michx.) was measured on these subplots to determine to what extent spruce was overtopped by the aspen that seeded in.

## RESULTS AND DISCUSSION

Black spruce seedlings averaged 800 per acre and 39 percent milacre stocking on the brushy site 2 years after full-tree skidding. These values are very low compared with the several thousand seedlings per acre and more than 80 or 90 percent stocking reported earlier for the nonbrushy site 2 years after skidding and for brushy and nonbrushy sites 2 to 4 years after broadcast burning (table 1). Probably the main reason black spruce reproduced poorly on the brushy site after skidding is because sphagnum moss, which usually remains moist after exposure, was sparse. Sphagnum seedbeds covered more than one-fourth of the ground on only 2 percent of the 1/4-milacre subplots on the brushy site compared with 64 percent on the nonbrushy site.

Because little snow covered the brushy site during skidding, a substantial amount of scarified and compacted seedbeds resulted. At first it appeared these nonsphagnum seedbeds would compensate for the shortage of sphagnum seedbeds, but the results show they did not. A long dry period the first summer probably caused considerable seedling mortality, especially on these nonsphagnum seedbeds. However, initial establishment should have been good the second summer had sphagnum seedbeds been abundant.

Associated reproduction was composed mainly of quaking aspen and paper birch on the brushy site 2 years after full-tree skidding, as on the nonbrushy site. However, these two species plus black ash (*Fraxinus nigra* Marsh.) and balsam fir were considerably more abundant on the brushy site (table 2). Further, whereas all stems on the nonbrushy site were new seedlings and less than 2 feet tall, on the brushy site 39 percent of the birch and nearly all of the ash were

| Nonbrushy | 2                    | 4,900                              | 800         | 0         | <100       |
|           | 7                    | 4,300                              | 5,400       | 0         | 200        |

sprouts, 58 percent of the fir were advance seedlings, and 1,100 stems per acre—mainly birch—were 2 to 7 feet tall. Finally, other vegetation such as grasses, sedges, and shrubs was much denser on the brushy site than nonbrushy site 2 years after skidding (fig. 1, A and B).

Thus black spruce seedlings were not only relatively scarce on the brushy site 2 years after full-tree skidding, but they also had much more vegetation to compete with than on the nonbrushy site. In addition, this vegetation produced a large amount of leaf litter—a poor seedbed. Leaf litter seedbeds covered more than one-fourth of the ground on about 80 percent of the  $\frac{1}{4}$ -milacre subplots on the brushy site compared with only 1 percent on the nonbrushy site. So even with continued natural seeding, satisfactory reproduction of black spruce—at least 60 percent milacre stocking of **established** seedlings (Johnston 1977)—either will not be obtained on the brushy site or will require several more years.

Black spruce reproduction on the nonbrushy site 7 years after full-tree skidding was almost identical to that reported earlier for 2 years—about 23,000 seedlings per acre and more than 90 percent milacre stocking (table 1). The number of quaking aspen and balsam fir seedlings also changed little, whereas paper birch seedlings were much more abundant at 7

Figure 1.—Trial areas after full-tree skidding: brushy site at 2 years (A), nonbrushy site at 2 years (B) and 7 years (C).

years than at 2 years (table 2). Although birch may have increased some from further seeding, most stems were likely present at 2 years but too small to be readily identified. Practically no more reproduction became established on the nonbrushy site despite 5 more years of natural seeding because the high number of black spruce and associated seedlings 2 years after skidding probably already occupied the good seedbeds.

The tallest black spruces on the nonbrushy site 7 years after skidding averaged less than half the height of the tallest quaking aspens—2.4 vs. 5.2 feet. However, spruce was generally growing well and many stems were not overtopped by aspen or birch (fig. 1, C). Thus release probably will not increase the growth of black spruce much on this medium quality site, but a trial is under way.

## MANAGEMENT IMPLICATIONS

Sound information is still limited on using full-tree skidding as a method of site preparation for reproducing clearcut black spruce by natural seeding. However, research and experience to date indicate that spruce seedlings will have the following relative stocking about 5 years after skidding under the peatland conditions shown:

| Site      | Sphagnum seedbeds   |                      |
|-----------|---------------------|----------------------|
|           | Abundant            | Sparse               |
| Nonbrushy | Good to overstocked | Understocked to poor |
| Brushy    | Poor to moderate    | Understocked to poor |

The two trials reported in this note represent two of the conditions in the above tabulation. The non-brushy site with abundant sphagnum had good seedbeds plus little competing vegetation, and so was overstocked—more than 10,000 spruce seedlings per acre (Johnston 1977). In contrast, the brushy site with sparse sphagnum had poor seedbeds plus much competing vegetation, and so was understocked—less than 60 percent milacre stocking.

Full-tree skidding has not been tried under the other two conditions in the preceding tabulation. Nevertheless, brushy sites with abundant sphagnum should have ample black spruce seedlings initially because of good seedbeds, but much competing vegetation is expected. So unless these seedlings are released, their stocking will likely be poor to moderate after a few years. Full-tree skidding on nonbrushy

sites with sparse sphagnum probably will result in poor stocking at best. This is because other mosses, particularly the feather mosses, usually dry up after clearcutting and become poor seedbeds (Johnston 1971, 1977).

Therefore, until further information is available, full-tree skidding is recommended for reproducing black spruce only on nonbrushy sites that have fairly abundant sphagnum seedbeds and adequate natural seeding. Exposed patches of sphagnum should have a milacre stocking of 60 percent or more, and seed should be provided by a mature spruce stand within 130 to 260 feet of the skidded area (Johnston 1977).

Broadcast burning of slash is still recommended for most other peatland conditions (Johnston 1977). In fact, severe burning is the only reliable practice at present to initially control competing vegetation on brushy sites and to improve nonsphagnum seedbeds. However, the popularity of full-tree skidding black spruce means few loggers are any longer willing to remove just the pulpwood and leave the slash evenly distributed for burning. Hence alternative practices such as planting or mechanical preparation of seedbeds need to be developed for those conditions where skidding alone will not result in satisfactory reproduction.

LIBRARY

**ABSTRACT.**—Container size and shape, potting medium, and genotype interacted to influence the growth of black walnut (*Juglans nigra* L.) seedlings. Larger containers tended to produce larger trees. In tall, narrow, vent-pipe containers, different proportions of peat and sand in potting media had no effect on total weight; a higher proportion of peat than of very fine sand in the potting media reduced the shoot/root ratio. In conventionally shaped pots, seedlings averaged 123 percent heavier when grown in a soil mix containing 75 percent peat and 25 percent sand than when grown in pure sand.

**KEY WORDS:** *Juglans nigra*, peat, sand, genotype, planting.

Continuing interest in intensive culture of black walnut (*Juglans nigra* L.) has prompted us to study techniques of growing black walnut seedlings in containers, not only for use as experimental plants, but also as trees potentially suitable for bench grafting or field planting in seed orchards or in special forest situations such as dry sites. We describe here the effects of pot volume, pot shape, and media containing different proportions of peat and sand on growth of black walnut seedlings raised from seed of 2 parent trees (Celmer 1970).

## MATERIALS AND METHODS

Seed was collected from 2 southern Illinois parent trees, one each in Jackson and Randolph Counties, cleaned and stratified in polyethylene bags for 6 months at 2C, germinated in peat-filled flats, and transplanted to pots in early June.

Seedlings were grown in 6 container types, including all combinations of 3 volumes and 2 shapes, as follows:

| Code | Approximate volume cm <sup>3</sup> | Conventional shape   | Cylindrical shape                | Code |
|------|------------------------------------|----------------------|----------------------------------|------|
| L    | 10,350                             | 10-inch tarpaper pot | 6 × 24-inch galvanized vent pipe | LL   |
| M    | 3,450                              | 8-inch plastic pot   | 4 × 24-inch galvanized vent pipe | ML   |
| S    | 1,150                              | 5-inch plastic pot   | 1 quart milk carton              | SL   |

The texture of the inner surface of pots may influence root development (Boden *et al.* 1969, Harris 1968) so the tarpaper pots were lined with 4-mil polyethylene to provide a smooth inner surface similar to plastic containers; holes were punched to allow drainage.

The media contained 4 proportions of very fine sand and shredded Canadian sphagnum peat as prescribed by Matkin and Chandler (1957): A—100 percent very fine sand; B—75 percent sand, 25 percent peat; C—50 percent sand, 50 percent peat; D—25 percent sand, 75 percent peat. At the time of mixing, 3.6 kg of dolomitic lime, 1.8 kg of 45 percent superphosphate, 0.3 kg of MgSO<sub>4</sub> and 37 g of fritted trace elements were incorporated in each m<sup>3</sup> of soil mix. Liquid 20-20-20 fertilizer was added weekly during the growing season and all pots were thoroughly watered 2 or 3 times each week. The seedlings were grown under 55 percent shade screens in a greenhouse with cooling that usually held day temperatures at a level not exceeding outdoor temperatures by more than 3C.

Treatments were replicated 3 times in a randomized complete block design. The containers were spaced sufficiently far apart to avoid crowding or shading of short pots by taller ones. After 6 weeks the blocks were interchanged and pots randomly rearranged within each block to reduce variation related to location in the greenhouse.

After 12 weeks, when the seedlings had dropped nearly all their leaves, total height of each seedling was measured to the nearest 0.5 cm and the plants were removed from the pots. Roots were washed free of potting medium and severed at the root collar. Shoots and roots were dried in an oven for 5 days at 48-50C, and weighed to the nearest 0.1 g.

Height, total weight, and shoot and root weights were analyzed following a conventional 3-way analysis of variance format (Celmer 1970).

## RESULTS

The black walnut seedlings responded to all the pot type, soil mix and genotype treatments (table 1). Seedlings from the Randolph County parent (fig. 1) grew taller than did those from the Jackson County parent in all pot types and in all soil mixes. Genetic growth differences were most pronounced in the 2 smaller pot sizes in which the Randolph County trees were not only taller but also averaged more than 40 percent heavier (table 2). The taller Randolph County seedlings probably represent a seed-size effect; the nuts were about 1.7 times as large as those from Jackson County.

The Randolph County seedlings weighed slightly less than those from Jackson County, especially in the 6-inch vent-pipe containers (LL) (table 2). The Randolph County trees tended to be heavier with

<sup>1</sup>Standard error of difference values: between any 2 individual treatment combinations—16.1 g; between any 2 pot-type means—5.7 g; between any 2 soil mix means—6.6 g.

while all but 2 percent of those grown from Randolph County seed trees possessed the single heavy taproot typical of most black walnut seedlings. These differences were not apparent at the time of transplanting. It may be that seedlings with multiple taproots are better adapted to growing in potting media with relatively high sand content.

Pot type and soil mix influenced seedling height and weight, jointly as well as separately. The trend toward larger plants in larger pots was obvious, except in the large tarpaper (L) pots (table 2). This deviation was not anticipated, because in a previous study (Funk 1971) mean weights of black walnut seedlings were nearly the same for plants grown in L and LL pots in soil mixes B and C (mixes A and D were not tested). The tarpaper pots (L) used in the earlier study were not lined with polyethylene, and we hypothesize that in this study growth was much poorer in the soil mixes with greater sand content because aeration was insufficient (Long 1932). A similar pattern of heavier seedlings associated with greater peat content is apparent for all 3 sizes of conventionally shaped pots but potting media had no influence on weights of plants in the cylindrical containers (fig. 2).

Occasional small seedlings had unusually high shoot/root ratios and, when these ratios were averaged for treatment means, some extreme values appeared. Thus, it was more realistic to sum the shoot and root weights for the seedlings in the 3 replications of each treatment and then calculate ratios based on these sums; the 2 seedling families were also pooled (table 3) because there was little difference between their ratios. These ratios of sums are no longer additive and the suitability of analysis of variance is thus limited.

Figure 2.—Weight of black walnut seedlings in relation to soil mix and container shape (3 container sizes and 2 genotypes pooled).

## DISCUSSION

Heavier seedlings generally had lower shoot/root ratios (tables 2 and 3); the correlation between shoot/root ratio and total weight was  $-0.69$ . Other workers have suggested that the shoot/root ratio varies with plant weight, although not necessarily in the same fashion for herbs, conifers, and broad-leaved trees (Jones 1968, Ledig and Perry 1966). Farmer

<sup>1</sup>Mean ratios were calculated from shoot and root sums for each treatment, not by averaging ratios in the body of the table.

(1970), studying larger plants of eastern cottonwood (*Populus deltoides* Bartr.) grown in loam with 2 soil moisture regimes, found that shoot/root ratio was related to plant weight. In a favorable soil moisture situation the correlation between plant weight and shoot/root ratio was negative while in a stressful situation the correlation was positive.

In an earlier pot study with black walnut seedlings, Funk (1971) proposed that changes in shoot/root ratio are not necessarily related to total plant weight, so we looked for sets of treatments in which total plant weight was relatively constant to see if any ratio differences were evident. Apparently total weight of walnut seedlings is not much affected by soil mix in cylindrical containers (fig. 2). Considering the 2 genotypes together, weight is especially stable in vent-pipe containers (LL and ML) (table 2). But shoot/root ratio of seedlings grown in soil mix D in vent pipes is about 29 percent lower than for those grown in the soil mix A (table 3). Acknowledging that analysis of variance of these ratios is not completely appropriate, we made such an analysis based on the 4 soil mixes, 2 sizes of vent pipes, and 2 seedling families. The effect of soil mix on shoot/root ratio was significant; a subsequent covariance analysis determined that the effect was not related to differences in total weight.

In the vent-pipe containers the proportions of peat and sand in the potting media influences shoot/root ratio of seedlings, and this effect was independent of weight. But we doubt that any of these soil mixes (except perhaps mix A, 100 percent sand) constituted "drastic treatments" (Ledig and Perry 1966) although Farmer (1970) suggests that the stress regime that led to a positive correlation between shoot/root ratio and weight of cottonwood seedlings could be considered as drastic.

Soil mix D produced relatively heavy and well balanced seedlings for most pot-type and genotype combinations, but it is also relatively expensive because of its high proportion of peat. It is not commonly used for growing container stock, but has excellent aeration and moisture-holding properties and has been suggested for pots and beds (Matkin and Chandler 1957). Our results suggest that media containing high proportions of peat or perhaps other organic materials (Klett *et al.* 1972) are desirable for growing walnut seedling in conventional pots and should be considered for producing planting stock in nursery beds. Peat-sand proportions of potting media should be less important when seedlings are grown in tall, narrow containers, unless field studies indicate that differences in shoot/root ratio are related to plantation performance.

**ABSTRACT.**—Soil properties (organic matter content, pH, texture, and microclimate) were related to early height growth of jack pine (*Pinus banksiana*, Lamb.), red pine (*Pinus resinosa*, Ait.), white spruce (*Picea glauca*, (Moench) Voss), and hybrid larch (*Larix leptolepis* x *Larix decidua*) planted in northern Wisconsin. Based on 2-year height growth, jack pine and hybrid larch performed best on these silty soils.

**KEY WORDS:** Organic matter, soil pH, jack pine, red pine, white spruce, hybrid larch.

Seedling early growth and survival are important aspects of forest management to ensure a quick economic return to the landowner. The optimization of tree growth by matching tree species to the most suitable soil is one management technique that shows promise in achieving that goal. Yet in order to do this, a clear understanding of the most influential soil factors is essential.

<sup>1</sup>A research study performed in cooperation with the Rhineland Forestry Sciences Laboratory, USDA Forest Service, North Central Forest Experiment Station, and the University of Wisconsin, Stevens Point, under Cooperative Agreement No. 13-544.

The importance and need for soil evaluation in relation to timber production has been emphasized in many reports. Stevens and Wertz (1971) estimated that the Nicolet area of Wisconsin has the potential for a 60 percent increase in sawtimber production by matching species to the soils. Therefore, we tested jack pine, red pine, white spruce, and hybrid larch in this area of northern Wisconsin to determine which soil properties were best related to early height growth of seedlings.

### METHODS

The experimental site is on the Nicolet National Forest in northern Wisconsin. The soil is Padus silt loam, an Alfic Haplorthod, of the coarse-loamy, mixed, frigid family, and consists of well-drained loamy sediments over sands and gravels on outwash plains, terraces, and pitted outwash.

The 1.0-ha site was cleared and disked in 1974 and hand planted with containerized seedlings in August, 1974. The site was divided into four blocks so each species occupied its own 0.25-ha block. Each species block (0.25 ha) contains 4 replications in a

randomized complete block design with 16 plots in each replication and 16 seedlings planted in each plot at a 2 meter spacing. In the fall of 1976, soil samples were extracted from the surface 15 centimeters (6 inches) of 60 randomly selected plots—17 from jack pine, 13 from red pine, 16 from hybrid larch, and 14 from white spruce. The average plot height growth was determined from those surviving from the original 16 seedlings planted in the plot.

Soil organic matter content was determined by the Walkley-Black method (Black 1965), soil texture by hydrometer, soil pH by potentiometer, and soil buffering with SMP buffer and potentiometer (Shoemaker *et al.* 1961). Soil data were then regressed with normalized height growth data.

It was hypothesized that microrelief variations could have affected seedling performance. To test for this, the site was stratified into high and low microsites for all species except larch, and an analysis of variance test was run on soil and growth data.

## RESULTS AND DISCUSSION

Higher soil organic matter was related to increased growth of jack pine, but not the other three species (fig. 1). This may suggest a greater growth potential for jack pine on soils with more organic matter. If a site is to be prepared for jack pine, methods that incorporate surface organic layers may be more desirable. The other three species grew well over the range of organic matter contents and may be advantageous for planting on soils whose surface organic layers have been depleted or completely removed.

Figure 1.—Relation of amount of soil organic matter to jack pine height growth.

Soil pH was significantly negatively correlated to red pine and white spruce growth (fig. 2). Both species grew better in the strongly acid (pH = 5.1 – 5.5) range. Jack pine and hybrid larch grew well over the range of pH's from 5.0 to 6.0.

White spruce and jack pine grew better on the coarser soil textures (fig. 3). Hybrid larch, however, grew better on the finer textures of the site (fig. 4). Other soil textural effects, such as surface runoff, soil compaction, infiltration, frost heaving, and aeration may have also had some effect on seedling growth.

Figure 2.—Relation of soil pH to red pine and white spruce height growth.

Figure 3.—Relation of amount of clay in soil to jack pine height growth.

Figure 4.—Relation of amount of silt in soil to larch height growth.

Height growth was significantly different between high and low microsites for jack and red pine. This might imply that microclimate differences, such as humidity, radiation, or temperature may have affected seedling growth. However, because soil properties were also significantly different, no specific conclusion could be drawn.

Jack pine and hybrid larch have better early growth and survival on these soils than red pine and white spruce. From the soil and growth relations, hybrid larch growth was not related to organic matter and had better growth in the loamier textures of the site. Jack pine was related positively to organic matter and negatively to percent clay, but nevertheless, good growth and survival were apparent.

Recent research has shown that red pine eventually outproduces jack pine on similar soils throughout the Lake States due to its greater basal area (Alban 1978). However, another recent study has

shown great potential for intensively cultured jack pine (Zavitkovski and Dawson 1978). In this study, jack pine biomass production was two to several times higher in intensively cultured silvicultural systems than in jack pine plantations grown under traditional silvicultural systems.

Site preparation methods appeared to cause considerable soil variation between plots. An evaluation of soil variation and stratification prior to planting may be advantageous in future tree planting experiments. By doing this, the experimental design could be adapted to anticipated growth differences.

## MINNESOTA LAND OWNERSHIP TRENDS, 1962-1977

Pamela J. Jakes, *Associate Resource Analyst,*  
and Alexander Vasilevsky, *Aerial Photo Interpreter*

**ABSTRACT.**—The distribution of Minnesota's commercial forest land among ownership classes has remained stable between 1962 and 1977. This note summarizes commercial forest ownership data by Forest Survey Unit for 1962 and 1977 and presents more detailed area statistics for Minnesota's 17 northern counties.

**KEY WORDS:** commercial forest area, commercial forest ownership.

Although the area of commercial forest land in Minnesota declined 11 percent between 1962<sup>1</sup> and 1977, the distribution of the land among ownership classes remained stable. In 1977, 54 percent of the State's commercial forest land was publicly owned; 46 percent was privately owned. 1962 area statistics showed the same distribution.

The largest public owner of commercial forest land in 1977 was the State of Minnesota, with 2.7 million acres. Commercial forest land in State ownership decreased 34.7 thousand acres between 1962 and 1977. This decrease is the result of the State acquiring less commercial forest land than it lost through

<sup>1</sup>Previously published 1962 statistics have been adjusted to be comparable with 1977 data. Adjustments were necessary because Survey Unit boundaries changed between surveys. Further adjustments were required because definitions have changed between surveys and survey procedures have improved. Improvements in survey procedures include better ground control during the selection of sample points from aerial photos and improved methods for determining unproductive forest land.

sales, expansion of the Boundary Waters Canoe Area (BWCA), creation of the Voyageurs National Park, and transfers to State Parks. The only ownership class to show an increase in commercial forest area was forest industry; forest industry commercial forest land holdings increased from 715.7 thousand acres in 1962 to 772.0 thousand acres in 1977.

All other ownership classes showed a decline in commercial forest area. The farmer and miscellaneous private ownership class lost the most acreage, 915.0 thousand acres, but national forests showed the largest percent decline, 20 percent. Most of the decline in national forest ownership is the result of commercial forest land in the Superior National Forest being transferred to the BWCA, where it is classified as productive-reserved.

Eighty-two percent of Minnesota's commercial forest land is located in the 17 northern counties that make up the Aspen-Birch and Northern Pine Forest Survey Units (fig. 1). Commercial forests account for 57 percent of the total land area in northern Minnesota. The 11.2 million acres of commercial forest land reported here in 1977 was 1.1 million acres less than that found in 1962. St. Louis County, the largest county in the region, accounted for the largest portion of the loss. Most of the decline in commercial forest land in St. Louis County was due to the expansion of the BWCA.

The majority of commercial forest land in the region is publicly owned. State and county and municipal ownership classes equally control approximately 41 percent of the commercial forest land in the region (4.6 million acres). The Superior and Chippewa National Forests contain 1.7 million acres of commercial

Figure 1.— Percent of commercial forest area in public ownership by Forest Survey Unit, Minnesota, 1977.

forest land, concentrated in six counties— St. Louis, Lake, Cook, Itasca, Cass, and Beltrami. The area of commercial forest land in the national forests declined in every county between 1962 and 1977 with the exception of Beltrami County. St. Louis and Lake Counties showed the largest decline in national forest area (161.7 thousand acres and 143.0 thousand acres, respectively). The Bureau of Indian Affairs, Bureau of Land Management, Fish and Wildlife Service, and other federal agencies administer the remaining 587.5 thousand acres of publicly owned land in the region.

Farmer and miscellaneous private owners control 3.5 million acres of commercial forest land in the region, 31 percent of the total. In northern Minnesota, commercial forest land accounts for 45 percent of the total land in this ownership category. Farmer and miscellaneous private commercial forest land declined 380.9 thousand acres between 1962 and 1977.

Forest industries own commercial forest land in most counties in the region, the exceptions being Mahnommen and Roseau Counties. Ninety-five per-

<sup>1</sup>Forest land that is producing or is capable of producing crops of industrial wood and that is not withdrawn from timber utilization by statute or administrative regulation

<sup>2</sup>Federal land that has been designated by executive order or statute as national forest or purchase units, and other land under the administration of the USDA Forest Service

<sup>3</sup>Federal lands other than national forests

<sup>4</sup>Land owned by states, or land leased by them for more than 50 years

<sup>5</sup>Land owned by counties, or local public agencies, or land leased by them for more than 50 years

<sup>6</sup>Land owned by companies or individuals operating primary wood-using plants

<sup>7</sup>Land privately owned by other than forest industry

Table 2.— Area of commercial forest land<sup>1</sup> by county and ownership, seventeen northern counties, Minnesota, 1962 and 1977

(In thousand acres)

<sup>1</sup>Forest land that is producing or is capable of producing crops of industrial wood and that is not withdrawn from timber utilization by statute or administrative regulation.

<sup>2</sup>Federal land that has been designated by executive order or statute as national forest or purchase units, and other land under administration of the USDA Forest Service

<sup>3</sup>Public land other than national forest land, including land administered by federal, state, or local public agencies

<sup>4</sup>Land owned by companies or individuals operating primary wood-using plants.

<sup>5</sup>Land privately owned by other than forest industry

cent of forest industry land is classified as commercial forest. Forest industries were the only ownership class in the region to show an increase in commercial forest land between 1962 and 1977. The increase was especially notable in Itasca County.

The sampling error for commercial forest areas from this survey is less than 1.5 percent (at one standard deviation) per million acres.

Table 3.— *Total land areas<sup>1</sup> by county and ownership, seventeen northern counties, Minnesota, 1962<sup>2</sup> and 1977<sup>3</sup>*  
(In thousand acres)

| County and year | All owners | National forest <sup>4</sup> | Other public <sup>5</sup> | Forest industry <sup>6</sup> | Farmer and misc. private <sup>7</sup> | County and year   | All owners | National forest <sup>4</sup> | Other public <sup>5</sup> | Forest industry <sup>6</sup> | Farmer and misc. private <sup>7</sup> |

<sup>1</sup>The area of dry land and land temporarily or partially covered by water such as marshes, swamps, and river flood plains; streams, sloughs, estuaries, and canals less than one-eighth of a statute mile in width; and lakes, reservoirs, and ponds less than 40 acres in area. Total land in all ownership by county is based on U. S. Bureau Census data

<sup>2</sup>U. S. Bureau of the Census, 1960.

<sup>3</sup>U. S. Bureau of the Census, 1970.

<sup>4</sup>Federal land that has been designated by executive order or statute as national forest or purchase units, and other land under administration of the USDA Forest Service

<sup>5</sup>Public land other than national forest land, including land administered by federal, State, or local public agencies.

<sup>6</sup>Land owned by companies or individuals operating primary wood-using plants.

<sup>7</sup>Land privately owned by other than forest industry.

# KILN SIZE AFFECTS ENERGY REQUIRED TO DRY LUMBER

Howard N. Rosen, *Research Chemical Engineer,  
Carbondale, Illinois*

GOVT. DOCUMENTS  
DEPOSITORY ITEM

JUN 26 1980

CLEMSON  
LIBRARY

**ABSTRACT.**—Energy requirements for lumber drying kilns can depend on kiln size and range from 18,000 Btu/lb water evaporated for a 10 board foot capacity kiln to 1,600 Btu/lb water evaporated for a 100,000 board foot capacity kiln.

The rising cost of fossil fuels is triggering a big push to conserve energy in the manufacture of wood products, so the lumber industry is taking a closer look at the energy consumption of wood-drying kilns. Wood moisture content and species, drying schedule, ambient conditions, leaks in the kiln, and kiln size all affect the amount of energy needed to dry the wood but many people are not aware of the great effect that kiln size has on the energy required to dry wood.

The energy used in a lumber dry kiln can be divided into the heat required to:

1. Raise the temperature of wood substance and water in the wood.
2. Evaporate the moisture (includes the energy to overcome the hygroscopic forces).
3. Raise the temperature of air and water vapor for venting.
4. Raise the temperature of the kiln.
5. Compensate for losses by conduction, radiation, and leaks through the walls, doors, and roof.

The magnitude of each category may vary somewhat depending on drying conditions, kiln type, and wood type, but usually the heat required to evaporate the moisture consumes the most energy.

To demonstrate the effect of kiln size on energy requirements, we theoretically calculated the heat required to dry wood in kilns of different capacity while keeping all operating conditions and kiln construction details the same. We assumed that southern pine of 0.48 green specific gravity dried from 105 to 10 percent moisture content at 190 °F in 82 hours. Ambient temperature was 70 °F and overall heat transfer coefficients were 0.15 Btu/hr ft<sup>2</sup> °F for the walls and roof and 0.80 Btu/hr ft<sup>2</sup> °F for the floor. The heat required to dry the lumber ranged from 1,600 Btu/lb of water evaporated in a 100,000 board foot kiln to almost 18,000 Btu/lb of water evaporated in a 10 board foot kiln (fig. 1).

As shown below for a 25,000 board foot kiln drying southern pine from 105 to 10 percent moisture content by a standard schedule, most of the energy was needed to evaporate moisture from the wood.

| Energy needed to:          | Total energy<br>(Percent) |
|----------------------------|---------------------------|
| Heat wet wood              | 8                         |
| Evaporate moisture         | 64                        |
| Heat air and water vapor   | 8                         |
| Heat kiln                  | 3                         |
| Compensate for heat losses | 17                        |

As kiln size changed, the energy to heat the wet wood, evaporate the moisture, and heat the air and water vapor per board foot of lumber remained nearly constant. Conversely, the energy required to heat the

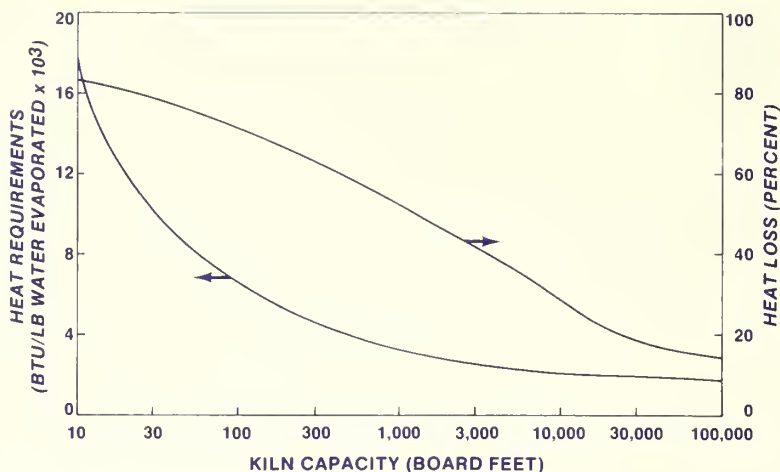

Figure 1.—Heat loss and heat required to dry 2-inch thick southern pine at 190°F in kilns of different capacity.

kiln and to compensate for heat losses changed significantly as kiln size changed. As kiln capacity decreased, heat loss increased. Heat losses accounted for more than 70 percent of the energy required to dry the lumber in kilns of 100 board feet or lower. Thus, energy requirements in Btu/lb water evaporated increased as kiln size decreased.

The energy required to heat the kiln and to compensate for losses is proportional to the surface area of the kiln, whereas the remaining heat requirements are proportional to the volume of the kiln. Thus, the ratio of the volume to surface area of the kiln affects energy requirements. Larger kilns have a greater volume/surface area than smaller kilns.

Experimental values of energy requirements obtained from the literature for high temperature drying of southern pine are consistent with the previous theoretical calculations (table 1).

Table 1.—Energy required to high temperature dry southern pine in different sized kilns—experimental data

| Kiln size | Volume per surface area | Btu/lb water evaporated | References |
|-----------|-------------------------|-------------------------|------------|
| 120,000   | 3.0                     | 1,630                   | Taylor     |
| 120       | 1.3                     | 6,770                   | Koch       |
| 3         | 0.3                     | 10,600                  | Rosen      |

The implications of the effect of kiln size on energy consumption are important when comparing different kilns or drying techniques to find which is the most energy efficient. When comparing different sized kilns for energy efficiency, make sure that kiln size is not the overriding influence for energy requirements. Also, specific statements on the effect of kiln conditions on energy requirements of small experimental kilns (1,000 board feet or less) may not apply to the larger commercial kilns (20,000 board feet or more).

## ENERGY VALUES OF NINE *POPULUS* CLONES

GOVT. DOCUMENTS  
DEPOSITORY ITEM

Terry F. Strong, Forestry Technician,  
Rhineland, Wisconsin

AUG 4 1980

CLEMSON  
LIBRARY

**ABSTRACT.**— Compares calorific values for components of nine *Populus* clones. The components include stem wood, stem bark, and branches. Also compares calorific values for clones of balsam poplar and black cottonwood parentages.

**KEY WORDS:** Calorific values, calorimetry, tree components, parentage

## METHODS

One sample tree was randomly selected from each of nine, 4-year-old *Populus* clones grown at Rhineland, Wisconsin. Each tree was divided into upper stem, lower stem, and branches. The bark was removed from the stem sections. All components were dried and ground in a Wiley mill to pass a 60-mesh screen. Ground samples were dried again at 70° C for at least 48 hours and pressed into pellets.

The calorific value (also called heat of combustion) of the samples was determined in an adiabatic oxygen bomb calorimeter using the standardized techniques of the manufacturer (Parr Instrument Company 1969<sup>1</sup>). Correction for fuse wire burn and heat of formation of nitric acid were deducted from the gross heat of combustion.

Analyses of variance and t-tests were used to test differences among clones and components. All tests were done at the 95 percent confidence level.

<sup>1</sup>Mention of trade names of the product does not constitute endorsement by the USDA Forest Service.

## INTRODUCTION

Because of its rapid growth, *Populus* may be a desirable genus to grow for energy in short rotation intensively cultured plantations (Zavitkovski *et al.* 1976). Inadequate information is available on energy values for *Populus* clones selected for this study or the individual tree components of *Populus* clones. Parr and Davidson (1922), Peterson *et al.* (1970), Reiners (1972), and James and Smith (1978) reported calorific values for different components of native *Populus*. Holt and Murphey (1978) determined calorific values for *Populus* clone NE-388 and recently Bowersox *et al.* (1979) reported calorific values for seven hybrid poplars.

## RESULTS

As shown below, mean calorific values of the *Populus* clones ranged from 4,636 to 4,755 cal/gm.

| 5272               | <i>P. nigra</i> x <i>P.</i><br>laurifolia, NE-1          | 4,726       |
| 5260               | <i>P. tristis</i> x <i>P. balsamifera</i>                | 4,730       |
| 5258               | Unknown  | 4,755       |

Although significant differences cannot be tested, balsam poplar clones (5262, 5263, 5272, and 5260) tend to have higher unweighted mean calorific values than black cottonwood clones (5377, 5326, 5331, and 5332).

Mean values of individual tree components are shown in the following tabulation.

| Component       | Mean cal/gm         |
|-----------------|---------------------|
| Lower stem bark | 4,604a <sup>3</sup> |
| Lower stem wood | 4,618a              |
| Upper stem wood | 4,703b              |
| Upper stem bark | 4,760bc             |
| Branches        | 4,813c              |

The clones were separated into two groups, each having at least one identical parent and their calorific values were tested for significant differences using a t-test.

<sup>2</sup>North Central Forest Experiment Station clone number.

<sup>3</sup>Means followed by the same letter are not significantly different at the 5 percent probability level.

| Component       | Black poplar | Balsam poplar      |
|-----------------|--------------|--------------------|
|                 | Cal/gm       | Cal/gm             |
| Lower stem bark | 4,572        | 4,604              |
| Lower stem wood | 4,628        | 4,612              |
| Upper stem wood | 4,709        | 4,693              |
| Upper stem bark | 4,674        | 4,825 <sup>4</sup> |
| Branches        | 4,779        | 4,833 <sup>4</sup> |

Clone 5258 was excluded from this test because its parentage is unknown. Clones with balsam poplar as one parent had significantly higher calorific values than black poplar clones in the upper stem bark and branches. Although clones do not differ significantly, balsam poplars tend to have a higher calorific value than black poplars. One possible reason could be the higher extractive content in balsam poplar's buds and bark. Upper and lower stem wood and lower stem bark were not significantly different between the two groups.

## DISCUSSION

Calorific values for stem wood in this study are similar to those presented by Holt and Murphey (1978) for bole wood of *Populus* clone NE-388, which ranged from 4,563 to 4,607 cal/gm, and to Bowersox *et al.* (1979) for composite wood and bark samples which averaged 4,659 cal/gm for seven *Populus* clones. Similarly, Peterson *et al.* (1970) reported calorific values of 4,591 cal/gm for trunk wood and bark of a *P. tremuloides* clone in Alberta. However, Parr and Davidson (1922) and Reiners (1972) found somewhat higher calorific values for bole wood—4,800 cal/gm for unspecified poplar wood, and 4,760 cal/gm for *P. grandidentata*, respectively.

Reiners (1972) also measured a mean calorific value of 4,800 cal/gm for branches, which agrees with the average for clones in this study. James and Smith (1978) separated twigs into bark and wood. The calorific value for twig wood was 4,550 cal/gm and that for twig bark was 5,040 cal/gm. The twig wood value is similar to my data for upper stem wood, but the twig bark value is higher than my value for upper stem bark.

In this study calorific values increased up the stem; branch calorific values were always higher than those of other components. This trend is substantiated by Madgwick (1970) and Hughes (1971).

<sup>4</sup>Significantly different at the 5 percent level.

I found that calorific values of wood samples did not differ significantly among clones. This agrees with Bowersox *et al.* (1979). Because stem wood is the largest component of the total tree (about 50 percent of the total weight), plantations at wider spacings may show differences due to their larger proportion of branches.

Calorific values of upper stem bark and of branches of clones with one balsam poplar parent were significantly higher than those of other components. Contradictory evidence was reported by Bowersox *et al.* (1979) for clone NE-388 whose one parent belongs to the balsam poplar group. However, the comparison was between a composite sample of bark from the total stem and wood, which would lower the calorific value for bark because bark from lower stem has a lower calorific value than bark from upper stem.

# FOREST AREA IN MINNESOTA, 1977<sup>1</sup>

Arnold J. Ostrom, Mensurationist

GOVT. DOCUMENTS  
DEPOSITORY ITEM

**ABSTRACT.**— Presents statistics on Minnesota's forest land area by county for 1977.

**KEY WORDS:** Commercial forest land, noncommercial forest land.

One out of every 3 acres in Minnesota is forested. These forested acres total 16.7 million acres in the State, almost 85 percent of which occur in a 17 county area in northern Minnesota encompassing the Aspen-Birch and Northern Pine Survey Units (fig. 1, table 4).

Forest land declines across Minnesota from 87 percent of all land in the northeast (Aspen-Birch Unit) to 3 percent of all land in the southwest (Prairie Unit). Cook County in northeast Minnesota is 99 percent forest, the most heavily forested county in the State.

Forest land, Statewide, declined 1.7 million acres or 9.4 percent between 1962 and 1977. A comparison of areas from the two inventories by geographical regions in the State shows that even more significant changes took place in certain sections of the State. The greatest reductions in forest area occurred in the Prairie and Central Hardwoods Units where the losses were 37 and 22 percent, respectively (table 1).

Commercial forests (land suitable for growing industrial timber products and not reserved from this use) now occupy 13.7 million acres or 82 percent of

<sup>1</sup>The sampling error of area for this survey was  $\pm 0.39$  percent for the 13.7 million acres of commercial forest land. The fourth forest inventory of Minnesota was conducted by the North Central Forest Experiment Station and the Minnesota Department of Natural Resources.

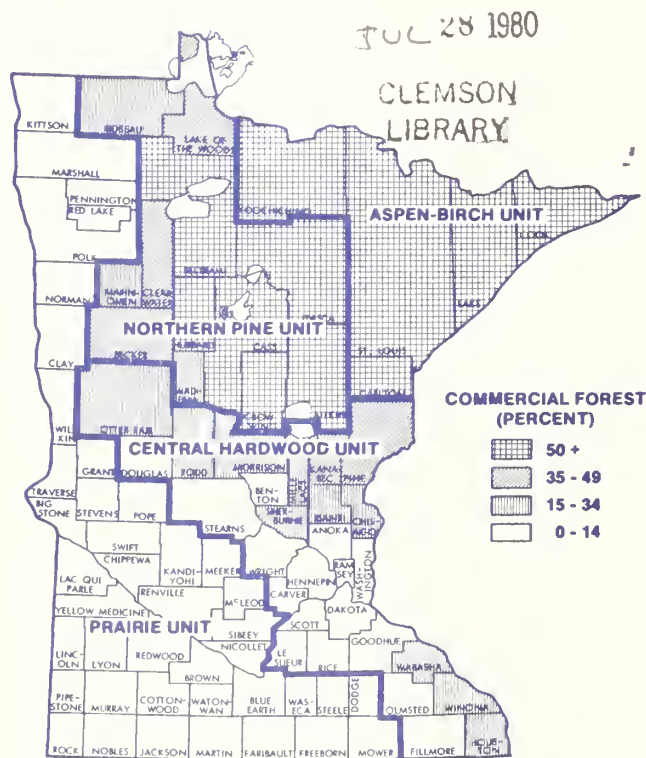

Figure 1.— Commercial forest area as a percent of land area by county, Minnesota, 1977.

Minnesota's forest land. Since the previous inventory in 1962, commercial forests have declined 1.7 million acres or 11 percent (table 2).

The patterns of change by geographical area follow those of total forest land except for the Aspen-Birch Unit. In this Unit, almost 500 thousand acres of forest land that formerly was classified as commercial

<sup>1</sup>1962 areas have been adjusted to conform to 1977 statistics because of changes in procedures and definitions between surveys.

has been reclassified productive-reserved. This is due to the creation of the Voyageurs National Park and the addition of the Portal Zone to the reserved section of the Boundary Waters Canoe Area of the Superior National Forest.

Noncommercial forest land totaled 3 million acres in 1977 (table 3). Of this amount, 1.8 million acres is forest land too poor to grow timber products suitable for industrial use. The remaining 1.2 million acres are productive but reserved for uses other than timber production, such as parks and other reserved recreation areas. The decline in noncommercial forest land between inventories can be attributed to a drop in unproductive forest acres.

<sup>1</sup>1970 Bureau of the Census estimates.

<sup>2</sup>Land at least 16.7 percent stocked by forest trees of any size, or formerly having such tree cover; excludes land currently developed for nonforest use such as urban or heavily settled residential or resort area, city parks, orchards, improved roads, or improved pasture land. The minimum forest area classified was 1 acre. Roadside, streamside, and shelterbelt strips of timber with a crown width of at least 120 feet and unimproved roads and trails, streams, and clearings in forested areas if less than 120 feet in width were classified as forest.

<sup>3</sup>Unproductive forest land incapable of yielding crops of industrial wood because of adverse site conditions, and productive public forest land withdrawn from commercial timber production through statute or administrative regulation.

<sup>4</sup>Forest land producing or capable of producing crops of industrial wood and not withdrawn from timber utilization by statute or administrative regulation.

PULPWOOD PRODUCTION<sup>1/</sup> IN THE LAKE STATES, BY COUNTY, 1979

James E. Blyth, *Principal Market Analyst*,

and W. Brad Smith, *Associate Mensurationist*

ABSTRACT.--Pulpwood production in the Lake States--Michigan, Minnesota, and Wisconsin--climbed to 5.55 million cords in 1979. Pulpwood production is shown by county and species group for these three States.

KEY WORDS: Residue, Michigan, Minnesota, Wisconsin.

Lake States pulpwood production advanced to 5.55 million cords in 1979. For the first time, logs, bolts, and wood residue used in manufacturing particleboard and waferboard are included in this annual report series. Wisconsin produced 2.11 million cords, Michigan 1.98 million cords, and Minnesota 1.46 million cords.

Ninety percent of the total output came from roundwood (including chips); the remainder came from mill residue such as slabs, edgings, veneer cores, and chips from those materials. Production from softwood and hardwood residue by State was:

| <u>State</u> | <u>Softwood</u>                       | <u>Hardwood</u> |
|--------------|---------------------------------------|-----------------|
|              | (Hundred standard cords,<br>unpeeled) |                 |
| Michigan     | 153                                   | 1,625           |
| Minnesota    | 427                                   | 752             |
| Wisconsin    | 485                                   | 2,107           |

Leading species harvested were aspen (2,298,000 cords), pine (870,000 cords), maple (443,000 cords), balsam fir (287,000 cords), and birch (266,000 cords).

Wisconsin continued to import large quantities of wood--516,000 cords from Michigan, 169,000 cords from Minnesota, 266,000 cords from other (primarily western) States, and 92,000 cords from Canada. Total exports from Wisconsin were only 85,000 cords.

<sup>1/</sup> Includes logs, bolts, and wood residue used in manufacturing particleboard and waferboard.

Counties producing more than 100,000 cords were Iron and Marquette in Michigan; St. Louis, Koochiching, and Itasca in Minnesota; and Oneida, Marinette, Price, Forest, and Sawyer in Wisconsin (table 1). These counties supplied one-third of the pulpwood produced in the Lake States from roundwood in 1979.

# MENSURATIONAL AND BIOMASS RELATIONS FOR POPULUS 'TRISTIS #1' UNDER INTENSIVE CULTURE<sup>1</sup>

Alan R. Ek, *Professor,*  
*Department of Forest Resources,*  
*University of Minnesota, St. Paul, Minnesota*

FEB 17 1981

LIBRARY

ABSTRACT.— Tree measurement data from plantations established in 1970 and 1973 and grown under intensive culture were used to establish various dimensional relations and biomass equations for *Populus 'Tristis #1'*. These equations subsequently have been used to estimate yields on study plots and for projections of future yields. They are presented here for others working with this hybrid and as a guide to model forms which might be utilized for other species.

KEY WORDS: tree measurement, plantations, hybrids, yield analysis.

Short rotation intensive culture (SRIC) studies begun in 1970 at the Hugo Sauer Nursery in Rhinelander, Wisconsin, have involved considerable growth and yield analysis. The principal variety used for studies of intensive cultural practices (fertilization, irrigation, etc.) to date has been *Populus 'Tristis #1'*. Dawson (1976) reviewed previous work on this variety. Ek and Dawson (1976) described earlier tree biomass equations developed for plantings established in 1970. The intent of this paper is to update that work by presenting equations developed from incorporating more recent data. Some of these data and the equations described here were used in yield

analyses by Meldahl (1979). The new data are from the same nursery site and fertilization and irrigation treatments described in these earlier papers.

## DESCRIPTION OF YIELD DATA

As the SRIC plantations have grown in number and tree sizes have increased, stem and branch analyses have evolved to consider more detailed stand and tree sampling techniques in developing biomass data. The earlier Ek and Dawson paper developed individual tree dry weight yield equations for stem wood, stem bark, branch wood, branch bark, branch tips, and leaves. The equations developed in that study were based on essentially complete analysis of small sample stems from three plots with square spacings of 0.2286, 0.3048, and 0.6096 m. Plots had sides measuring 5.0, 5.2, and 5.5 m. Sample trees were drawn from the interior of each plot each year. This led to 235 observations of tree dimensions and associated stem wood and bark weight. (There were fewer observations for other tree weight components.) Over 80 percent of these data were obtained at ages 1 and 2 years. The remaining 20 percent came from trees at ages 3 and 4 years. In addition to recording total tree height and basal diameter (2.5 cm above the base of the root collar), the trees were separated into the six above mentioned components. Harvesting was done in late summer at the time of maximal leaf biomass.<sup>2</sup> These components were then oven dried at 70 C and weighed to the nearest 0.01 g.

<sup>1</sup>Research supported by the College of Agricultural and Life Sciences, University of Wisconsin Madison, the College of Forestry, University of Minnesota, and the USDA Forest Service, North Central Forest Experiment Station under cooperative Research Agreement 13-421. The author gratefully acknowledges assistance from David H. Dawson and staff of the USDA Forest Service, Forestry Sciences Laboratory, Rhinelander, Wisconsin, in all phases of the study.

<sup>2</sup>A small but undetermined number of leaves were lost prior to harvest.

These data subsequently are referred to as those from the 1970 plantings.

Additional larger plantings were established in June 1973 with square spacings of 0.3048, 0.6096, 1.2192, and 2.4384 m. These plots were 8 to 16 rows wide and had 24 to 36 trees per row. As in 1970, 20-cm cuttings were planted. Trees subsequently were selected and harvested or otherwise observed on these plots at ages 3 and 4 years to augment the data from the 1970 plantings. Additionally, two of the larger trees from the 1970 plantings were harvested in the fall of 1976 to augment information on larger stems. Together, these data subsequently are referred to as those from 1973 plantings. This data set included 20 to 34 trees, depending on the variable of interest.

The 1973 data were developed by selecting and harvesting three trees from the 0.3048, 0.6096, and 1.2192 m spacings near the peak of the third growing season (9 trees), and one more stem from each spacing at the end of that season (3 trees). In addition, two trees were drawn from each spacing at the end of the fourth growing season (6 trees). Also, two trees drawn from the 1970 plantings at the end of the seventh growing season were included in this data set. Except for the two trees from the 1970 plantings, the selected stems were a stratified sample, with stratification based on diameter outside bark at breast height (D). Equal numbers of stems were selected randomly from each of three D classes within each spacing. To minimize the influence on remaining stems, however, this harvesting was concentrated at one end of each plot, excluding border trees. The two trees from the 1970 plantings were purposively selected from among the largest stems from the plots established in that year. These stems were obtained from the interior of the 0.3048 and 0.6096m spacings. These 20 stems are grouped together here because of their similar analysis as described below.

Laboratory analysis of the stems then was conducted using four or more systematically located 150-mm sections along the stem, beginning at 25 mm above the ground. Section measurements included green diameters inside and outside bark at each end, oven dry (70 C) weight of wood and bark, and the height of each section base above ground. Total stem height (H), D, and diameters outside bark every 30 cm up the stem also were determined. Section volumes for specific gravity determinations were developed using Smalian's formula for frustrums of paraboloids.

Branch observations included measurement of the diameter (at 25 mm from stem base) of all branches

and the height of the branch base above ground. Long and short branches then were selected randomly from each of the above stem sections for length, specific gravity, and dry weight of wood and bark determinations. Total branch wood plus bark dry weights were observed directly, but dry weight of wood and bark components were estimated, using the total branch weights multiplied by wood and bark specific gravities determined on sections. Section size and location procedure was similar to those used for the main stem. Leaf dry weight determinations were made only for the nine trees measured at the peak of the third growing season and only for the selected long and short branches on those stems.

An additional 14 trees were purposively selected from the 1973 plantings to cover the range of tree sizes present. These were observed only for height and basal diameter (2.5 cm above ground) and inside and outside bark diameters at breast height at the end of the third growing season.

Another data set, referred to as 1974 observations, involved determining diameters outside bark at six to eight systematically located positions along the stems of 30 trees. These trees were selected at random in the spring of 1974 from the 1970 plantings. Observations on these stems included basal diameter (2.5 cm above ground), diameter at 0.15 m, 0.30 m, 1.37 m, and at approximately 1.0 m intervals to the tip, and total height. Diameters at 0.15 m from the tip also were recorded. These data originally were intended for development of a stem taper equation, but even when combined with the 1973 data, extrapolation to larger tree sizes via the various equations tested was tenuous. Consequently, the development of taper equations was postponed and the 1974 data were used only to aid quantification of stem biomass.

## ANALYSIS

The above yield data were analyzed by nonlinear regression analysis to develop two types of equations. The first set, primarily mensurational, was used to convert the 1970 data to a form compatible with the 1973 data (this involved estimating breast height diameter from basal diameter), and to develop tree component weights for the 1973 and 1974 data sets from the various subsample information on these trees. The second type of equations given describe tree dry weight or biomass components as a function of tree D and total height H. These equations are described in tables 1 and 2.

Computing stem weight for wood and bark components for the 1973 and 1974 data involved applying

the diameter inside bark and specific gravity equations (table 1, equations b, c, and d) to the periodic diameter outside bark data available for these stems. The section volumes were obtained using Smalian's formula.

Tree branch wood, branch bark, and leaf weights were obtained using equations developed from the branch data to express weight as a function of branch and tree characteristics. The model form used was:

$$w = b_1 d^{b_2} (H-h)^{b_3} (H/D)^{b_4 + b_5}$$

where:

- w = branch component weight,
- d = branch diameter outside bark at 25 mm from base,
- h = height to base of branch and the  $b_i$  are constants

Summing predictions over all branches on the stem provided the total branch component weight used for these trees. Details of developing these equations are given by Ek (1979). Only average specific gravities of branch wood and bark are given in table 1, as these characteristics were not well correlated with branch and/or tree dimensions.

The use of the biomass equations given in table 2 is recommended for trees 0.5 to 9.1 cm D. For smaller trees, the equations based on basal diameter and total height given by Ek and Dawson (1976) are recommended. With those equations, branch wood plus tip weight is analogous to the branch wood term estimated in this report. For extrapolation to trees larger than 9.1 cm, the equations given here based on D should provide useful approximations. Use of table 2 equation (a) for stem wood weight together with the stem specific gravity equation (g) for larger tree sizes leads to total stem volume values comparable to those given in table 3 of Gevorkiantz and Olsen (1955). The fact that table 3 is known to fit a wide range of species suggests the feasibility of extrapolation via equations given in table 2.

The model form used for tree biomass in table 2 is:

$$w = b_1 D^{b_2} H^{b_3} \quad (1)$$

This model is an extension of the common allometric model. It has a long history of use in forest yield analyses (Husch, *et al.* 1972). The use of weighting procedures here produced a slight improvement in fits for the smaller tree sizes. Other models were tested but this form consistently performed best. An attempt to introduce a spacing term via the model form:

$$w = b_1 D^{b_2} H^{b_3} S^{b_4}$$

where S was the initial stand spacing in m produced negligible improvement in fits.

From a physical standpoint, model (1) also may be rewritten as:

$$\begin{aligned} w &= b_1 D^{b_2-2} H^{b_3-1} (D^2 H) \\ &= F (D^2 H) \end{aligned} \quad (2)$$

In this form, the first term on the right hand side (F) of (2) may be viewed as a combination of basic constants, stem form, and specific gravity factors applied to the dimensions of a cylinder of height = H and diameter = D. Barring sharp changes in stem form and specific gravity not associated with tree size, this formulation suggests considerable extrapolative potential. Extrapolation is not encouraged, but may be necessary for some yield projections until more data are available. Of the equations in table 2, the one for leaf weight, because of its limited data base in terms of stand age, is perhaps least suitable for extrapolation.

The equations in table 2 also may be used with slight adjustment, to approximate yields above a 0.15 m stump. The total stem biomass for the higher stump for 20 trees from the 1973 plantings ranged from 90 to 98 percent of that for the 0.03 m stump. Percentage differences in yields for the two stump heights also decreased with increasing tree size. Percentage differences in biomass for branch components between the two stump heights were negligible.

**ABSTRACT.**—The effects of cutting diameter on early survival and growth of several *Populus* clones were studied in field tests in Wisconsin and Michigan. Generally, large diameter cuttings survived and grew better than small diameter cuttings. Response differences among clones were evident.

**KEY WORDS:** vegetative propagation; tree plantations; dormant hardwood cuttings.

Plantations of fast-growing clones of *Populus* hybrids and selections in the sections of Aigeiros and Tacamahaca are most efficiently established by planting dormant cuttings from 1-year-old stems. These clones possess preformed root primordia that enable them to root and grow when planted on favorable sites (Shapiro 1958, Smith and Wareing 1974). However, to obtain best survival and growth it is necessary to select the most vigorous cutting material. Because the factors responsible for cutting vigor are not well defined or understood, the propagator or nursery manager must rely on a variety of criteria such as stem age, collection time, overall appearance, and dimensions to collect the best material.

The possible correlation between cutting diameter and establishment success has been investigated only to a limited extent in *Populus*. Generally, it has been found that small diameter cuttings obtained from the tip portions of shoots have fewer preformed root primordia (Smith and Wareing 1974) and do not root or grow as well as those from basal portions (Bloomberg 1959, 1963, Hartmann and Kester 1975, Ying and Bagley 1977). However, overall results of this kind of research seem to have been inconsistent.

To determine the importance of cutting diameter on early field performance of some promising *Populus* clones, we studied the effect of a range of diameter classes on first-year survival and shoot growth at two locations in the Lake States.

### MATERIALS AND METHODS

Two separate studies were begun in 1978— one in northern Wisconsin at the North Central Forest Experiment Station's Harshaw Experimental Farm near Rhinelander, Wisconsin, and the other in East Lansing, Michigan, at the Michigan State University Tree Research Center.

Data from both experiments were subjected to analysis of variance. Means from the Rhinelander

study were compared using the method of Newman and Keuls and means from the East Lansing study were compared using the Least Significant Difference method (Snedecor and Cochran 1967).

## Rhineland Study

The three clones selected for the Rhineland study were *Populus* cv. 'Betulifolia' x *P. trichocarpa* Torr. & Gray (NE 299);<sup>1</sup> *Populus nigra* L. x *P. laurifolia* Ledeb. (NE 1), and *Populus tristis* Fisch. x *P. balsamifera* L. cv. 'Tristis #1' (NC 5260). One-year-old coppice shoots of each clone were collected in January and cut into 20 cm lengths. The cuttings were then sorted into diameter classes of <6, 6, and 9 to 16 mm (measured in the middle of the cutting), sealed in heavy polyethylene bags, and stored at 2.8°C until planting.

On June 20, the cuttings were hand planted about 15 cm deep in a fertile, sandy loam soil in an area prepared by discing. Cuttings were planted 0.3 m apart within the row; rows were 0.6 m apart. The design was a randomized complete block design with 20 cuttings of a diameter class in each of 3 replications. Plots were hand weeded and irrigated as needed. Survival and shoot height were recorded for the various treatments at the end of the first growing season on September 21.

## East Lansing Study

The three clones selected for the East Lansing study were *Populus* cv. 'rasumowskyana' x *P. cv. 'incrassata'* (NE 58); *Populus x euramericana* (Dode) Guinier cv. 'I45/51' (NC 5328), and *Populus deltoides* Bartr. x *P. cv. 'caudina'* (NE 353). Hardwood cuttings 25 cm long were harvested from 1-year-old coppice shoots in March and stored in polyethylene bags with moist sphagnum moss at 2°C. Cuttings were sorted into small-end diameter classes just before planting as follows: <6, 6 to 10, 10 to 13, 13 to 16, and 16 to 19 mm.

Cuttings were hand planted about 23 cm deep in nursery beds on June 30 and July 3. The sandy loam soil was rototilled several times before planting. Cut-

tings were planted at 0.3 by 0.6 m spacing in a split plot, randomized block design with eight cuttings per plot and four replications. Plots were hand weeded and irrigated as needed. Three weeks after growth began, each cutting was pruned to just one shoot. Plants were sprayed once with the insecticide Sevin in mid-August to control the cottonwood leaf beetle (*Crysmela scripta*). Height and survival of shoots were measured every 2 weeks beginning on July 21. On September 25, shoots of two trees from each treatment combination were randomly selected, harvested, oven-dried at 70°C, and weighed.

## RESULTS AND DISCUSSION

In both the Rhineland and East Lansing studies, cutting survival and shoot length growth were significantly influenced by cutting diameter (tables 1 and 2). In general, large diameter cuttings survived better and produced taller shoots than small diameter cuttings. Large diameter cuttings also produced shoots with a greater dry weight than small diameter cuttings in the East Lansing study (table 2).

Clones differed distinctly in their response to cutting diameter. For example, clone NC 5328 showed 100 percent survival regardless of the size of cuttings, whereas clone NC 5260 showed only 38 percent survival of small diameter cuttings and 93 percent survival of large diameter cuttings. The contrast in these two clones is also shown by the shoot length data. The difference in shoot growth between large and small cuttings for clone NC 5328 averaged only 14 percent but for clone NC 5260 was 250 percent. The four other clones represented a spectrum of intermediate responses. The ranking of clones, based on response to cutting diameter, showed clone 5260 most responsive followed by NE 1, NE 299, NE 58, NE 353, and NC 5328. These results are in accordance with Bogdanov (1968), who showed substantial variation in the survival and growth response to cutting diameter among six *Populus* clones.

Differences in height between cuttings of various diameters for the three clones used in the Michigan experiment were recorded from July 21 onward (fig. 1). In general, shoots from small cuttings were  $\frac{1}{3}$  to  $\frac{2}{3}$  as tall as those from large cuttings during the first 5 weeks after planting. This is the period when unrooted cuttings are most susceptible to environmental stress and weed competition (Aird 1962, Schreiner 1945). The sooner cuttings become established and gain dominance over weed competition, the greater will be the first-year success of a plantation.

<sup>1</sup>Northeastern Forest Experiment Station (NE) numbers are used where possible to designate clones mentioned in the text. Otherwise, North Central Forest Experiment Station (NC) numbers are used. NE 1 = NC 5272; NE 299 = NC 5331.

<sup>1</sup>For each clone, means followed by the same letter are not significantly different at the 5 percent probability level (least significant difference).

In the present experiments the difference in growth rate between cuttings of various diameters was less after the first 5 weeks (fig. 1). However, if weeds had not been controlled or if supplemental water were not applied, differences in growth rate between cuttings of various sizes probably would have been greater. Again, contrasts between clones were evident. Clone NE 58, which was moderately responsive to cutting diameter, showed differential growth throughout the first 7 weeks, whereas the unresponsive clone NC 5328 evidenced little effect of cutting size on growth after the first 5 weeks. Clone NE 353 showed a more complex growth response but was generally intermediate between NE 58 and NC 5328.

## CONCLUSIONS

Establishment of plantations of *Populus* hybrids showing high survival and good growth requires that many conditions be met, one of which is to use high quality hardwood cutting stock. An important measure of cutting quality revealed by this study is diameter—survival and growth generally increase with increasing cutting diameter. Although clones differed in their response to cutting diameter, cuttings <6 mm average diameter of all *Populus* clones should not be used for field plantings.

## ACKNOWLEDGMENT

The authors thank Mr. Gary A. Johnson for his technical assistance in the East Lansing portion of this study.

## PESTICIDE PRECAUTIONARY STATEMENT

This publication reports research involving pesticides. It does not contain recommendations for their use, nor does it imply that the uses discussed here have been registered. All uses of pesticides must be registered by appropriate State and/or Federal agencies before they can be recommended.

CAUTION: Pesticides can be injurious to humans, domestic animals, desirable plants, and fish or other wildlife— if they are not handled or applied properly. Use all pesticides selectively and carefully. Follow recommended practices for the disposal of surplus pesticides and pesticide containers.

TIMBER VOLUME IN MINNESOTA, 1977. DOCUMENTS DEPOSITORY ITEM

Arnold J. Ostrom  
 Mensurationist

MAY 8 1981

**ABSTRACT:** Presents statistics on Minnesota's growing-stock and sawtimber volumes by county for 1977. Includes a map showing growing-stock volume classes by county.

**KEY WORDS:** Growing stock, sawtimber, species, counties.

Minnesota's 13.7 million acres of commercial forest land supported 11.4 billion cubic feet of growing-stock<sup>1</sup> in 1977. This is an increase of 21 percent since the last inventory in 1962, despite a decrease in the commercial forest land base of 11 percent. However, this increase was not distributed proportionally among all species. Volume in softwoods increased a modest 3 percent while volume in hardwood species jumped 32 percent in the 15 years between inventories. These increased volumes reflect a maturing of Minnesota's forest with average growing-stock volume per acre increasing from 613 cubic feet (7.8 cords per acre) in 1962 to 836 cubic feet (10.6 cords per acre) in 1977. Growing stock trends are shown in the following tabulation:

| Growing stock | <sup>2</sup> 1962    | 1977   |
|---------------|----------------------|--------|
|               | (Million cubic feet) |        |
| Softwoods     | 3,384                | 3,477  |
| Hardwoods     | 6,060                | 7,977  |
| Total         | 9,444                | 11,454 |

<sup>1</sup>Net volume of all live merchantable trees 5 inches d.b.h. and larger from the stump to a variable 4-inch top diameter outside bark of the central stem. Does not include limbs or cull tree volume.

<sup>2</sup>Figures have been adjusted from those published after the 1962 survey to conform to 1977 volumes because of changes in survey procedures and definitions.

Aspen is the most abundant species in Minnesota accounting for 30 percent of the growing-stock volume. Its volume increased by 22 percent between surveys. Paper birch, the second most plentiful species in the State, showed an even more dramatic increase of 50 percent. The third most prominent species, balsam fir, increased 17 percent in the 15 years between inventories. The volumes of the other two species in the top five, spruce and jack pine, declined by 12 and 17 percent, respectively. These five species make up three-fifths of the growing-stock volume in Minnesota. The following tabulation shows growing-stock volumes of these species.

| Species     | Growing stock<br>(Million cubic feet) |
|-------------|---------------------------------------|
| Aspen       | 3,411                                 |
| Paper birch | 1,274                                 |
| Balsam fir  | 894                                   |
| Spruce      | 718                                   |
| Jack pine   | 594                                   |

Included in the growing-stock volume are 25 billion board feet of sawtimber,<sup>3</sup> expanded from 15 billion in 1962. This is an even more rapid accumulation of volume than growing stock, with softwoods expanding by 39 percent and hardwoods by 84 percent.

<sup>3</sup>Net volume of live merchantable sawtimber trees (softwoods 9.0 inches d.b.h. or larger and hardwoods 11.0 inches d.b.h. and larger) from the stump to a point in the central stem at which utilization for sawn products is limited by large branches, forks, or other defects, or by a diameter outside bark 7.0 inches for softwoods and 9.0 inches for hardwoods.

Average sawtimber volume per acre increased from 965 to 1,797 board feet between surveys. Sawtimber trends are shown in the following tabulation:

| Sawtimber | 41962                             | 1977   |
|-----------|-----------------------------------|--------|
|           | (Million board feet) <sup>5</sup> |        |
| Softwoods | 6,133                             | 8,531  |
| Hardwoods | 8,742                             | 16,077 |
| Total     | 14,875                            | 24,608 |

As in growing stock, aspen is by far the leading sawtimber species in Minnesota, comprising 25 percent of the volume. Aspen also showed the most rapid growth, increasing by 170 percent in the 15 years between surveys. Red pine is the second-ranked sawtimber species, accounting for 8 percent of the total volume. Red oak, elm, and jack pine, in that order, are the other most abundant sawtimber species in Minnesota. Volumes of all these species have increased since 1962. These five species account for over one-half of the State's sawtimber volume. Shown below are the sawtimber volumes of these species:

| Species   | Sawtimber<br>(Million board feet) <sup>5</sup> |
|-----------|--|
| Aspen     | 5,975  |
| Red pine  | 1,953  |
| Red oak   | 1,820  |
| Elm       | 1,607  |
| Jack pine | 1,566  |

The major concentrations of timber are found in a 17-county area in northern Minnesota encompassing the Aspen-Birch and Northern Pine Survey Units (fig. 1). This area contains more than 80 percent of the State's growing stock volume and 77 percent of the State's sawtimber volume. Ninety-seven percent of the State's pine growing-stock volume and 99 percent of its spruce volume is found here. The distribution of growing-stock volumes by survey unit is shown below:

| Survey Unit      | Growing-stock volume<br>(Percent) |           |
|------------------|-----------------------------------|-----------|
|                  | Softwoods                         | Hardwoods |
| Aspen-Birch      | 54.3                              | 33.0      |
| Northern Pine    | 43.4                              | 44.0      |
| Central Hardwood | 2.2                               | 18.5      |
| Prairie          | 0.1                               | 4.5       |
| Total            | 100.0                             | 100.0     |

These statistics are based on results from the cooperative Forest Inventory conducted from July 1974 to July 1978 by the North Central Forest Experiment Station and the Minnesota Department of Natural Resources. This is one of a number of reports that will be prepared to make these resource statistics available.

Sampling error (at one standard deviation) is estimated to be  $\pm 1.04$  percent for the total growing stock volume in the State of 11.4 billion cubic feet. Sawtimber sampling error is estimated to be  $\pm 1.85$  percent for the State total of 24.6 billion board feet.

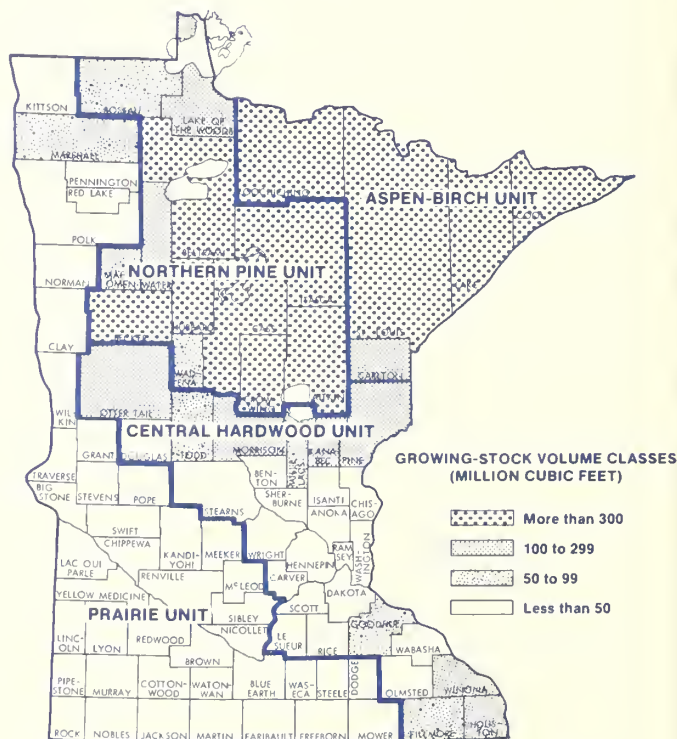

Figure 1.—Growing stock volume in Minnesota counties, 1977.

<sup>4</sup>Figures have been adjusted from those published after the 1962 survey to conform to 1977 volumes because of changes in survey procedures and definitions.

North Central Forest Experiment Station,  
East Lansing, Michigan

**ABSTRACT.**—Summer moisture contents and factors for converting fresh plant weights to oven-dry weights were determined for selected herbs, ferns, and small shrubs commonly found on upland sites in northern Lower Michigan. Sampling was done weekly from mid-June through early September 1978, following the period of major plant growth. Average summer moisture contents ranged from 120 percent for blueberry (*Vaccinium* spp.) to 370 percent for wild lily-of-the-valley (*Maianthemum canadense*). Generally, moisture content decreased through the summer. Moisture content averages and trends were similar for plant groups sampled in both northern Lower Michigan and northeastern Minnesota. Herbaceous fuel moisture percentages computed using the 1978 National Fire Danger Rating System for the same time period showed a similar general trend but were significantly lower than observed values.

**KEY WORDS:** forest fuels, fuel modeling, plant biomass, fire danger.

The moisture content of shrubs, ferns, and herbaceous plants can greatly influence wildland fire behavior. In fact, live fuel moisture input is required for predicting fire behavior (Rothermel 1972, Albini

1976, Deeming *et al.* 1977). Moisture content information is also used to compute factors for converting field green weights to dry weights, which are used to determine forest fuels, range forage, wildlife foods, or simply biomass.

Estimating both herbaceous and woody live fuel moisture is part of the National Fire Danger Rating System—NFDRS (Deeming *et al.* 1977, Burgan 1979). However, Loomis *et al.* (1979) found that estimates produced by the NFDRS algorithm for predicting herbaceous live fuel moistures were significantly lower than observed field measurements of live fuel moisture. This suggested a need for further study of live fuel moisture contents under other eastern forest stands.

This paper reports on live fuel moisture contents found in northern Lower Michigan and compares them to live fuel moisture contents measured in Minnesota (Loomis *et al.* 1979). Live fuel moisture estimates based on the NFDRS are also examined.

### METHODS

Above-ground parts of living herbs, ferns, and small shrubs were collected weekly in Roscommon County, Michigan. Eight plant species or species

groups were studied. Samples were collected from within a forest stand or from small openings. The two principal overstory species were jack pine (*Pinus banksiana* Lamb.) and northern pin oak (*Quercus ellipsoidalis* Hill). The stands were approximately 50 years old. Soils were predominantly sandy. The first samples were collected on June 13 and the last on September 6, 1978.

Ten 5-gram samples of fresh material were collected per plant group. These were sealed in metal cans, transported to the laboratory, and oven-dried at 105°C for at least 16 hours. An average moisture content (expressed as percent of oven-dry weight) for each plant group was determined. In addition, factors for converting green weights to oven-dry weights were computed (conversion factor = oven-dry weight ÷ green weight).

The time series of weekly moisture contents were examined and compared on the basis of magnitude, seasonal trend, and location. Graphical analysis, multiple comparisons, t-tests, covariance analysis, and regression analysis were the principal analytical methods used. The NFDERS live fuel moistures were computed using weather data for the Houghton Lake Airport, which is located about 10 miles from the data collection area.

## RESULTS AND DISCUSSION

Average seasonal moisture contents ranged from 370 percent for wild lily-of-the-valley (*Maianthemum canadense*) to 120 percent for blueberry (*Vaccinium* spp.) (table 1). Moisture contents decreased during the summer sampling period. Therefore, we stratified the data into "early" (June 13 to July 24) and "late" (July 25 to September 6) season and computed separate averages for each.

Species differences were examined with a multiple comparison plot. Most of the plant group responses were different, but means of certain plant group combinations were not significantly different. Linear regressions of changes in moisture content yielded significant relations for all species groups except grass<sup>1</sup> (table 2). All regressions, including that for grass, represented expected response.

A multiple comparison plot was made for six of the eight plant groups studied in Michigan that were also studied in Minnesota during the summer of 1976 (fig. 1). Eight of 11 pairs tested were not significantly different. Moisture contents for Minnesota wild lily-of-the-valley (late), large-leaved aster (early), and

<sup>1</sup>Covariance analysis supported these combinations.

Table 1.—Moisture contents, standard errors, and conversion factors for some grasses, forbs, and small shrubs in northern Lower Michigan

Figure 1.—Multiple comparison of Minnesota and Michigan summer living plant moisture contents using Tukey's honestly significant differences (HSD)

*Rubus* (late) were significantly higher than those for Michigan.

The NFDRS-computed herbaceous and woody live fuel moistures for climate class 3 were calculated for the sampling period.<sup>2</sup> Weekly mean NFDRS moisture contents were compared to the weekly moisture contents of *Carex* spp. (low moisture content), bracken fern (medium moisture content), and large-leaved aster (high moisture content) (fig. 2). No inventory was available for determining an average

<sup>2</sup>Climate class 3 was used because it is recommended for use throughout most of the eastern forest area.

Figure 2.—A comparison of National Fire Danger Rating System (NFDRS) climate class 3 herbaceous fuel moistures and some actual herbaceous moisture contents in Roscommon County, Michigan, 1978.

herbaceous fuel moisture for Michigan as was done in the 1976 Minnesota study. However, it is obvious that the composite herbaceous fuel moisture content of any particular area can vary greatly depending upon numbers of various plant species. All herbaceous species we studied had moisture contents exceeding the NFDRS estimates, similar to results in Minnesota. Thus, use of the NFDRS herbaceous fuel moistures is not acceptable when absolute fuel moisture estimates are needed.

The overall summer weather was similar for Michigan in 1978 and Minnesota in 1976 in that it was unusually dry. Thus, the plants at both locations were subjected to above average moisture stress. Samples at both locations were taken shortly after mid-day when plants would most likely be having difficulty maintaining full turgor pressure.

The moisture contents of blueberry and *Rubus*, which are common small woody plants, were compared with NFDRS woody fuel moisture (fig. 3). Both had statistically significant decreasing moisture trends through the season. In contrast, the NFDRS woody fuel moisture shows an increasing trend. Therefore, actual measurements again are best when absolute fuel moisture estimates are required.

Figure 3.—A comparison of National Fire Danger Rating System (NFDRS) climate class 3 woody fuel moistures and some actual small woody plant moisture contents in Roscommon County, Michigan, 1978.

## CONCLUSIONS

The NFDRS algorithms may be used to compute herbaceous and woody fuel moistures to estimate relative fire behavior trends for a season. However, they should not be used when absolute values are required because they are subject to error, particularly for herbaceous fuel moistures. The average moisture content values reported here are appropriate when general estimates are needed for planning over broad areas and for large trends in Lake States northern forests. The conversion factors are suitable for dry weight determination when approximate estimates are sufficiently accurate. These results further suggest that moisture response characteristics of similar plant species may be nearly uniform throughout the Lake States northern forest.

ABSTRACT.—It has been suggested that on-site surveys of users fail to measure crowding accurately because long time users who knew the area before the "crowds" came tend to feel the most crowded, and thus do not return. Such "displaced" users would not be included in current on-site survey samples. Results from a limited test at the Sylvania Recreation Area in Michigan do not support this "displacement thesis." However, further research is needed in other settings to test this hypothesis more fully.

KEY WORDS: Wilderness areas, social carrying capacity, social surveys, displacement, crowding.

As use continues to intensify in backcountry recreation areas, wildland managers are under increasing pressure to establish user limitation levels, or "carrying capacities," and somehow to arrive at and justify these levels through objective analysis. "Social carrying capacity" commonly is defined as that aspect of total carrying capacity concerned with the number of other people users can tolerate and still maintain a quality experience.

Numerous studies of social carrying capacity have pointed to the weak relation between perceived crowding and satisfaction (Heberlein 1977, Randal 1977, Shelby and Nielson 1975, Lee 1975). Heberlein (1977) suggested two important processes which may contribute to this weak relation. First, old time users who knew an area before the "crowds" came tend to feel the most crowded, and thus do not return. Since these sensitive past users are no longer in the area, current on-site social surveys cannot measure their dissatisfaction. Second, many of the current users are there for the first time and have no previous experience with the area. Therefore, they tend to accept whatever level of density they experience as normal. For the purpose of discussion, we will call these two processes the "displacement effect" and the "uninitiated newcomer effect." Heberlein suggests that, as a result of these two processes, indicators from on-site social surveys will show continued high levels of satisfaction and unconcern about overcrowding as actual use and density continue to increase. Heberlein indicates that these dynamics invalidate on-site social surveys of perceived crowding and satisfaction. But do the "displacement effect" and the "uninitiated newcomer effect" really exist, or are they pronounced enough to invalidate on-site survey measures?

<sup>1</sup>This research was funded by the North Central Forest Experiment Station, USDA Forest Service.

There is some empirical evidence supporting the "uninitiated newcomer effect" (Vaske *et al.* 1980, Nielson *et al.* 1977). However, there is no direct evidence available regarding the displacement thesis. Heberlein and co-workers have provided indirect evidence that the displacement phenomenon may exist. In a study of the Apostle Islands they found early users of the area perceived more environmental damage and viewed increases in the number of users negatively (Vaske *et al.* 1980). There was no measure of actual displacement from the area, but researchers did find certain islands were avoided by long term users who perceived more crowding. Similar "avoidance" behavior was noted in a study of Bois Brule River users (Heberlein and Vaske 1977). While this evidence is suggestive, avoidance behavior within an area is different than complete displacement and does not constitute a direct test of the displacement thesis. This paper reports one attempt to directly measure the displacement thesis in a study of backcountry users at the Sylvania Recreation Area in the Ottawa National Forest in Michigan.

## STUDY METHODS

The study is composed of two surveys. The first survey was an on-site survey of users conducted in the summer of 1978. The second was a phone survey of past users of the area. Each of these surveys was used to test the above hypotheses in different ways.

In the on-site survey, a sample of 321 backcountry campers were interviewed at the Sylvania Recreation Area during July and August of 1978. Interviews were conducted during the morning and afternoon. One of these two time frames was selected randomly for each day of the 2 month period except Wednesday. A 100 percent sample was taken during each randomly selected time frame. Interviewers were placed at the two major access points (Clark Lake and Crooked Lake) to interview campers as they returned from their backcountry trips. A proportional sample also was selected from the registration cards of people who camped on Whitefish Lake, an area which has a separate remote access point that is not used frequently. These users were interviewed by phone within 10 days after their trip.

On-site surveys of current users would not be sufficient to test Heberlein's theories. Thus, a major part of this study consists of a phone survey of past users of the area. From the registration cards from the 1973 season, a random sample of users was selected. Extensive efforts were made to locate anyone who had moved. Out of a total sample of 520 persons, 301 (57 percent) were interviewed. Of the remaining 219 persons, 168 (32.2 percent) had no phone or could not be

located, and 49 (9.4 percent) were located but could not be reached. There were two refusals (0.4 percent).

## THE STUDY AREA

The Sylvania area is managed as a multiple use backcountry recreation area by the U.S. Forest Service. It currently is proposed for wilderness designation in the RARE II proposals by the Forest Service. This 20,000 acre backcountry is a unique area with very clear oligotrophic northern lakes. Use is limited in the backcountry to 87 designated sites. These sites are developed with latrines to insure minimum impact on the water quality. With these technological improvements, social carrying capacity is a more restrictive factor than ecological carrying capacity in the area.

We should note that the Sylvania Recreation Area may be a special case for testing the displacement thesis. Although we can distinguish early users from newcomers there, the time span involved is shorter than in many backcountry areas, since the Sylvania area was established in 1968. The displacement thesis thus needs further testing in areas with a longer history of use.

We asked in what years (1967-1978) individuals had visited the area, which permitted us to categorize users into various temporal user types. "Old timer dropouts" were defined as persons who came to the area in 1973 and at least one previous year, but who had not returned in the last 5 years. "One timers" were defined as those who came in 1973 only and had not come either before or since that year. "Recent regulars" were defined as those who came in 1973, 1974, and at least 1 year since then. "Long time regulars" were defined as persons taking at least one trip before 1973, during 1973 and 1974, and one trip between 1975 and 1978.

We asked "old timer dropouts" and "one timers" who had not returned to the area their reasons for not coming back. The responses were put into categories including "overcrowding." This allowed us to assess the importance of crowding as a reason for not returning in relation to other factors. A direct question also was asked of all respondents about overcrowding during the 1973 trip. This question was: "During your 1973 trip(s) would you say the backcountry was 'very overcrowded,' 'somewhat overcrowded,' 'not crowded,' or 'don't know?'"

Since we were asking people to remember events from 5 years ago, recall accuracy might have been a problem. Thus, we attempted to measure recall accuracy on some aspects to see how much this might affect results. We knew that all respondents had

come in 1973, but when we called these individuals we said only that we were interviewing "past" users. We then asked what years they had visited Sylvania and checked to see if they accurately recalled their 1973 visit. Sixty-five percent of the respondents remembered the exact year of their visit, while 89 percent remembered within 1 year of the correct year. Thus, while there may be some distortion due to recall problems, recall accuracy was fairly good, at least to the extent we were able to measure it.

## RESULTS

If Heberlein's notions about the "displacement effect" and the "uninitiated newcomer effect" are correct, we should expect the following:

1. Old timer dropouts should have felt more overcrowded than other users.
2. Newcomers should feel less crowded than old timers.
3. Persons who have not revisited the area since 1973 should tend to list overcrowding as the most important reason for not returning.

Table 1 presents data to test the first two expectations from the phone survey of 1973 users. The two newcomer types, the "one timer" and the "recent regular," showed a slight tendency to be bothered less by crowding than did the two types of old timers. However, the percentage differences are small and are not significant statistically. In comparing the two types of old timers, we found the regulars (those who came before and after 1973) felt more crowded in 1973 than did the old time dropouts (table 2). Contrary to what we expected from the displacement thesis, old timers who came back after 1973 actually felt more crowded in 1973 than old timers who did not return. In conclusion, there are no sharp differences between "old time dropouts" and "uninitiated newcomers" in their perception of crowding, and perception of crowding is not associated with old time users dropping out.

These findings from the phone survey of 1973 users are valuable because they reflect the attitudes of those who did not return after 1973. However, one drawback of the 1973 data is that the use levels during that year were quite low, therefore, the proportion of persons feeling crowded also was low. In the survey of 1973 users, only 11.5 percent of the sample felt crowded. The displacement phenomena may occur only at higher densities where more users feel crowded. That is, there may be a threshold of crowding beyond which the displacement process becomes more pronounced.

Table 1.—*Perception of crowding by temporal user type (from the phone survey of 1973 users)*

| Temporal user type <sup>1</sup> | Perception of crowding |                  |             | Total        |

<sup>1</sup>Includes both One Timers and Old Timer Dropouts

We can test this partially from the on-site survey of 1978 users. In the on-site survey of 1978 users, densities were higher and more people felt crowded (22.1 percent). The 1978 survey data does not allow us to detect directly those who did not return after 1978. However, we do have a surrogate measure. Respondents were asked whether they planned to return to

the Sylvania area in the next 5 years. While this does not predict behavior precisely, a vast majority of respondents had definite future plans. Only two (0.6 percent) respondents answered the question "don't know."

Table 3 presents the results for the relation between crowding and intent to return. The displacement thesis would predict those who felt crowded would be less likely to say they would return. Here again the data do not support the displacement thesis. There is no relation between feeling crowded and the intent to return. Very few persons plan not to come back. Of those who felt crowded, the vast majority still plan to return, suggesting that crowding will not create further displacement. This further refutes the displacement thesis and possibly expands it to somewhat higher density levels.

Table 3.—*Relation between perceived crowding and intention to return to Sylvania (from the on-site survey of 1978 users)*

| Intention to return<br>or not to return<br>to Sylvania | Perception of crowding |                |                |

| Total  | (70)<br>100%           | (247)<br>100%  | (317)<br>100%  |

## IMPLICATION

This study found that, at the Sylvania Recreation Area, older users who have not returned to the area since 1973 do not have significantly greater perceptions of crowding than other users, and that newcomers in 1973 did not feel significantly less crowded than older users. Persons who did drop out, did not do so because of crowding. These findings were supported from results of the 1978 survey which involved higher densities and a greater degree of perceived crowding.

We must, of course, be cautious in generalizing these findings. It is possible the dynamics Heberlein identifies may be present in other areas or at still higher levels of use. The displacement thesis should be tested in other areas, especially those with higher

densities and longer histories of use. What may emerge from these cumulative findings from different areas, are hypotheses about conditions under which the displacement phenomenon will be more or less pronounced.

Rather than abandoning social survey measures of social carrying capacity, perhaps the results need only be used more sensitively. For instance, where surveys show great variability in perception of crowding, establishing a single uniform carrying capacity may not be advisable, especially where the "uninitiated newcomer effect" may raise average capacity. Rather, managers should think in terms of establishing "variable use level capacities" through spatial or temporal zoning. In situations where the displacement phenomena may be more pronounced, the extent of "old timer dropout" concern about crowding should be assessed and incorporated to help determine low density zones.

**ABSTRACT.**—White spruce seedlings—20, 19, 18, and 17 inches tall—were selected among 2-2 transplants; controls from the same beds averaged 7.7 inches tall. After 18 years in the field, the selected seedlings continued to have a 30 percent height growth advantage over the controls. This note discusses how to incorporate super spruce seedlings into a tree breeding program.

**KEY WORDS:** *Picea glauca*, juvenile selection, tree improvement and breeding, seed production areas, vegetative reproduction.

White spruce (*Picea glauca* (Moench) Voss) seedlings selected on the basis of superior nursery growth maintained their growth advantage after 18 years of field testing. Nursery selection of super seedlings may be one way to make long-term breeding programs more efficient.

### METHODS

In 1956, 696 white spruce seedlings were selected in 2-2 transplant beds of the Consolidated Paper Company's nursery east of Rhineland in northeastern Wisconsin. The selected seedlings were grouped into four height classes: 17, 18, 19 and 20 inches (table 1). Controls were picked at random from seedlings next to the selected ones and averaged 7.7 inches tall. The seedlings were paired and planted in

rows on the company's Experimental Forest east of Rhineland. No statistical design other than the pairing was used. The site was not ideal for white spruce because it lacked uniformity in soil moisture and air drainage. Much of it was wet and frosty early in the growing season.

Tree heights were measured in 1961 and 1962 and frost injury scored in 1964. After 7 growing seasons in the field, the selected seedlings had maintained their superiority over the controls. (King *et al.* 1965).

Flushing of the buds was scored in May 1973 using six classes of bud development as described by Nienstaedt and King (1969). Total tree heights were measured later that fall.

### RESULTS

By 1973, 84 percent of the seedlings had survived and 74 percent of the pairs were intact. There were no important differences in survival between the selected seedlings and the controls (table 1).

The selected seedlings continued to have a 30 percent height growth advantage over the controls on the average. This, according to the t-test on the pairs, is highly significant statistically, unlike the effect of seedling height class. The 7-year heights were highly correlated with 18-year heights with *r* values exceeding 0.8. Not only are the selected trees taller than the controls, but the frequency distribution of the two groups is normal (fig. 1). In the selected

<sup>1</sup>t-test for heights.

population, 296 trees are 12 feet or smaller while 289 are taller than this mean height; in the control population, 489 trees are 12 feet or smaller and only 100 are taller.

Minor differences in the time of flushing were not significant and are not shown.

## DISCUSSION

Reducing the age at which reliable phenotypic selections can be made will substantially reduce the cost and increase the effectiveness of forest tree improvement programs. Several options for incorporating juvenile selections into such programs are available depending on program objectives and funding.

If early production of improved planting stock is the objective, vegetative propagation of the selected seedlings may be the option to try. Such programs are now underway for Norway spruce in Germany (Kleinschmidt 1974, Kleinschmidt *et al.* 1973), Denmark (Roulund 1976, 1979) and elsewhere. In addition, mass production techniques for juvenile white spruce material are now being developed in Canada and the United States (Rauter 1974, Nienstaedt 1979, Armson *et al.* 1980). Using perfected rooting techniques and hedges to maintain rooting ability, about 200 selections should produce 300,000 to 500,000 plantable trees annually after 5-7 years (Nienstaedt 1979).

Incorporating the juvenile selections into multi-generation breeding programs will require testing as in our study. Control seedlings can be omitted from such tests if suitable land is scarce. The test site should be uniform and capable of producing good white spruce.

If early seed production is an objective and funding limited, developing the test planting into a seed production area (SPA) could be the best approach. The test in our study covers a little less than 1 acre with an original spacing of about 6 feet by 5 feet. Because SPA spacing should be about 20 feet by 20 feet, the test planting would need to be thinned to 104 trees in the 16 foot height class or taller: 97 select trees and seven control trees (fig. 1). A broad genetic base would be required from the beginning of the program; the selection and breeding strategy would depend on the populations available, the breeding zone and the agencies involved.

To assure full development of the crowns, thinning should begin as soon as flowering does—on most sites it could probably begin at about 12 years from seed and end at 20 years. By this approach, further genetic improvement could be achieved with repeated two-stage mass selection in the nursery and plantation representing advancing generations of the population.

If maximum yield improvement through a long-term intensive breeding program is the main goal and funding not a limiting factor, the approach

Figure 1.—Frequency distribution in 1-foot height classes of white spruce trees grown from select and control nursery stock—18 years after field planting.

should be to incorporate a few of the best trees as parent trees in the initial breeding population. These trees should be selected in the field test as soon as flowering begins. For example, in our study, the selections—those larger than the mean height of the nursery selections plus two standard deviations—would include 14 trees in the 20 foot height class or taller (table 1); 13 trees would represent the nursery selections and one tree the controls.<sup>1</sup>

<sup>1</sup>The breeding population would have included many more selections.

The results suggest that with a selection differential of 125 percent (selected seedlings 125 percent taller than average) or more, white spruce seedlings can be selected at 4 years in the nursery and about three-fourths of them should continue to be superior growers. There is no evidence that more rigorous selection—equivalent to selecting only 20 inch seedlings in the population studied—would be worthwhile.

Although the ultimate proof of genetic superiority will require progeny testing of the selected trees, the high correlation between height at 7 and 18 years is evidence that these super seedlings may be genetically superior.

**ABSTRACT.**—Calcium cyanamide, a nitrogenous fertilizer, was evaluated in new plantings of black walnut, white ash, and white oak seedlings and 2- and 3-year-old white oak and white ash trees, respectively. Only the growth of black walnut seedlings and white ash trees was improved by  $\text{CaCN}_2$ . Some weeds were controlled by  $\text{CaCN}_2$ , but the amount of weed control was not significantly influenced by the rate of  $\text{CaCN}_2$ . Only the survival of white oak seedlings was affected by  $\text{CaCN}_2$ .

**KEY WORDS:** weed control, fertilization, seedling survival, old field, mulch.

Black walnut (*Juglans nigra* L.), white ash (*Fraxinus americana* L.), and white oak (*Quercus alba* L.), like most hardwood species, have specific site requirements and demand intensive care to produce satisfactory growth. Their growth on abandoned agricultural land is often poor, possibly because of low fertility and weed competition for nutrients and moisture.

Fertilization of planted hardwood seedlings often intensifies weed competition, offsetting fertilizer benefits (von Althen 1976). If plantations of these three species are to be successful, weeds must be controlled at least the first 2 years. Both mechanical and chemical weed control methods have proven to be successful, but some can be expensive. Some chemicals used for weed control may also be toxic to hardwoods.

Calcium cyanamide ( $\text{CaCN}_2$ ), an alkaline nitrogenous fertilizer containing about 22 percent nitrogen and 20 percent lime, may also act as a herbicide (Auchmoody and Wendel 1973). In the soil,  $\text{CaCN}_2$  hydrolyzes principally to calcium hydroxide and urea with the formation of unstable intermediate compounds that are toxic to some seeds and plants.

In the spring of 1976, we began a study on abandoned fields in southern Illinois to evaluate the effects of  $\text{CaCN}_2$  on weeds and on growth of black walnut, white ash, and white oak when applied immediately after planting and in established plantations.

### METHODS

Two abandoned fields, one adjacent to Hutchins Creek and the other to Kinkaid Lake in southern Illinois, were selected as planting sites for black walnut, white ash, and white oak seedlings. A dense cover of broadleaf weeds was well established in both fields. Soils in the Hutchins Creek planting are Cape and Piopolis silty clay loams. These bottomland soils have slow permeability and high available moisture content. Soil in the Kinkaid planting is moderately well drained Ava silt loam. In addition, we located plantations of white ash and white oak that had received  $\text{CaCN}_2$  at rates ranging from 0 to 1,120 kg/ha.

The fields were tilled and 150 seedlings of each species were planted at a 3.7 x 3.7 meter spacing. The following treatments were immediately applied in a completely randomized design: (1) control, (2) hoeing three times per season and (3) CaCN<sub>2</sub> at rates of 448 kg/ha, 672 kg/ha, 896 kg/ha, and 1,120 kg/ha. CaCN<sub>2</sub> and hoeing were applied over a 1.2 m diameter area and repeated before weed growth began (about March 15) in the second and third years. Hoeing was repeated again about mid-June each year of treatment.

For the trees, 150 3-year-old white ash and 150 2-year-old white oak were selected. Both plantings had been cultivated twice a year for the previous 2 years. Tall fescue (*Festuca arundinacea*) had invaded the white ash planting and broadleaf weeds had invaded the white oak planting. Spacing was similar to that of the seedlings. Soil in the white ash planting is Wake-land silt loam. This site is nearly level and has poor to moderate drainage. The white oak planting is on a moderately well drained, gently sloping site with Alford silt loam soil. The trees averaged 1.5 and 1.4 m tall and 2.1 and 1.3 cm in diameter at 15 cm above ground for white ash and white oak, respectively.

Instead of hoeing, we placed a 1.2 m square of black plastic around each tree and anchored it with soil. Otherwise, the treatments and time of application were the same as those used for the seedlings.

Height and diameter (15 cm above ground) for seedlings and trees were measured at the beginning of the study and at the end of each growing season for 4 years. Weed cover was estimated about June 1 and August 1 of each year. Treatment effects were examined by an analysis of variance and Scheffe technique (Snedecor and Cochran 1967).

## RESULTS AND DISCUSSION

### Survival

Survival differences were small. Only white oak seedlings were adversely affected by CaCN<sub>2</sub>, generally the higher the rate of application the lower the survival (fig. 1). Many of the surviving seedlings suffered repeated dieback. Survival of the white oak trees was not affected, suggesting white oak is more tolerant when older.

### Weed Control

Both hoeing and black plastic mulch provided much better weed control than CaCN<sub>2</sub> at any rate (fig. 2). The most noticeably suppressed weeds on all

Figure 1.—Average survival of seedlings and trees 4 years after initiation of CaCN<sub>2</sub> treatment. Species statistically analyzed separately; a is different from b for the same species at the 0.05 level.

Figure 2.—Average weed control provided by treatment in three hardwood species in June 1978.

sites were ragweed (*Ambrosia artemesulfolia* L.), yellow nutgrass (*Cyperus esculentus* L.), goldenrod (*Solidago ulmifolia* Muhl.), bitter dock (*Rumex obtusifolius* L.), and plantain (*Plantago* sp.). The amount of annual weeds present increased toward the end of the season in all plantings. The amount of fescue in the white ash tree planting was reduced by CaCN<sub>2</sub> at all rates during the second and third growing season.

Weeds that develop from underground parts were suppressed by CaCN<sub>2</sub> during the early part of the growing season, but by late July grew vigorously, perhaps in response to reduced competition and additional nutrients. These species included bermuda grass (*Cynodon dactylon* (L.) Pers.), dewberry (*Rubus* sp.), ground cherry (*Physalis heterophylla* Ness), trumpet creeper (*Campsis radicans* (L.) Pers.), and wild potato vine (*Ipomoea pandurata* L.).

## Growth

Hoeing and plastic mulching generally produced the greatest height growth, except for black walnut in the Kinkaid planting and white oak trees. We suspect that plastic caused a heat buildup in the soil that retarded white oak growth, because there were no visible symptoms of stress or poor nutrition. CaCN<sub>2</sub> did not increase diameter growth except for white oak seedlings at the 448 kg/ha rate (tables 1 and 2).

Walnut grew faster at Hutchins Creek than at Kinkaid, probably because of better soil fertility and moisture conditions. However, CaCN<sub>2</sub> at the two highest rates did increase the height growth of walnut at Kinkaid significantly over the control. The combination of weed control and nutrients supplied by CaCN<sub>2</sub> seemed to be more beneficial in the Kinkaid planting than at Hutchins Creek, where only the hoed treatment was significantly different from other treatments.

The poor overall growth of white oak seedlings was probably due to the stunting effect of CaCN<sub>2</sub> on many of the surviving seedlings (table 1). Further, the height growth of white oak trees was not significantly affected by CaCN<sub>2</sub>.

Height growth of white ash seedlings treated with CaCN<sub>2</sub> was on the average no better than the control, but the higher rates of CaCN<sub>2</sub> significantly increased height growth of white ash trees over the control (table 2). CaCN<sub>2</sub> treated trees had greener foliage than other trees, suggesting better nutrition.

No attempt was made to separate the contributions of fertilizer and weed control to height growth. But

<sup>1</sup>Values for each species in the same column followed by the same letter are not significantly different (0.05 level) as determined by the Scheffe technique.

because the higher rates of  $\text{CaCN}_2$  were usually associated with better growth and there was not much difference in weed control, we concluded that height growth above that reported for the 448 kg/ha rate may be attributed to  $\text{CaCN}_2$  as a fertilizer.

## Summary

Black walnut seedlings and white ash trees grew faster in response to broadcast  $\text{CaCN}_2$  treatments than white ash and white oak seedlings or white oak trees. The faster height growth was usually associated with the higher rates of  $\text{CaCN}_2$  application (886 and 1,120 kg/ha). Both growth and survival of white oak seedlings were reduced when treated with  $\text{CaCN}_2$ . Results also suggest that white ash seedlings may be sensitive to  $\text{CaCN}_2$ .

Both the amount of weed control and weed growth varied according to site conditions. Differences in weed control between the lowest and highest rates of

$\text{CaCN}_2$  were insignificant. Residual weed control was equal to about half the weed control of the previous year.

# TREE BIOMASS ESTIMATES FOR MINNESOTA'S ASPEN-BIRCH FOREST SURVEY UNIT

Gerhard K. Raile, Associate Mensurationist,  
and Pamela J. Jakes, Associate Resource Analyst

**ABSTRACT.**—Live tree biomass estimates are presented for five counties of northeastern Minnesota. Tree biomass is given in green tons for forest types and species groups.

**KEY WORDS:** Volume, tops and limbs, cull, growing-stock, boles.

An increasing demand for wood fiber, advances in wood technology, and other changes in the Nation's forest resources have spurred interest in complete tree utilization. Such developments require a measure of total tree volume that includes more than just merchantable volume. Estimating tree biomass is the first step in estimating the total wood volume on commercial forest land.

Tree biomass, including the bark, is made up of five components:

1. **Growing-stock boles.**—the above-ground volume in growing-stock trees from a 1-foot stump to a variable 4-inch top diameter outside the bark (t.d.o.b.).
2. **Growing-stock tops and limbs.**—the above-ground volume in growing-stock trees from a 1-foot stump, excluding the growing-stock bole.
3. **Cull tree boles.**—the above-ground volume in cull trees from a 1-foot stump to a 4-inch t.d.o.b.
4. **Cull tree tops and limbs.**—the above-ground volume of cull trees from a 1-foot stump, excluding the cull bole.

5. **1- to 5-inch d.b.h. trees.**—the total above-ground volume of all trees 1 to 5 inches in diameter at breast height.

In Minnesota, estimates of tree biomass on commercial forest land outside the National Forests were obtained during the fourth Minnesota Forest Inventory (dated 1977). The recently completed Superior National Forest Inventory (dated 1979) has provided tree biomass estimates for that forest. Information from the two surveys has been combined to estimate the tree biomass on commercial forest land in the Aspen-Birch Forest Survey Unit (Carlton, Cook, Koochiching, Lake, and St. Louis Counties).

## METHOD

Tree biomass was estimated with the following method: First, net cubic foot volumes were converted to green tons by using weight conversion factors for each species (Markwardt 1930). The weight of the bole bark was then computed using bark correction factors for individual species, the gross volume of the bole, and an average bark weight of 37 pounds per cubic foot. Tops and limbs for growing-stock and cull trees were estimated as 45 percent of the gross bole volume (Young *et al.* 1976). Finally, the biomass for trees less than 5 inches d.b.h. was computed from a regression equation fit to Young's tree weight table (Young *et al.* 1976). This regression equation uses d.b.h. to estimate total above-ground biomass as 80 percent of the above- and below-ground biomass.

## FINDINGS

Tree biomass in the Aspen-Birch Forest Survey Unit was estimated at 250.8 million green tons in 1978, or about 43.5 green tons per acre of commercial forest land. Sixty-five percent of the Unit's biomass is made up of growing-stock trees (table 1). Biomass in 1- to 5-inch d.b.h. trees accounts for more than one-quarter of the Unit's total tree biomass. The distribution of tree biomass among the five components differs for softwoods and hardwoods (fig. 1).

Hardwood tree species make up most of Minnesota's tree biomass. Of the 149.3 million green tons of hardwood tree biomass, 108.9 million green tons are in aspen and paper birch. Softwood tree biomass is concentrated in balsam fir and black spruce. More than 50 percent of the black spruce tree biomass is in 1- to 5-inch d.b.h. trees.

The 250.8 million green tons of tree biomass in the Aspen-Birch Unit equal 11.8 billion cubic feet. Tree biomass in growing-stock boles totals 5.3 billion cubic feet. Data from the fourth Minnesota Forest Inventory and the Superior National Forest Inventory show that net growing-stock volume in the Unit is 4.4 billion cubic feet. The difference between

biomass cubic foot volume in growing-stock boles and the net growing-stock volume in cubic feet is the bark component of biomass. Bark accounts for almost 20 percent of the growing-stock bole biomass.

Forty-eight percent of the biomass is in stands less than 51 years old (table 2). The importance of small diameter trees in supplying biomass is shown in the distribution of biomass among diameter classes (table 3). Twenty-six percent of the total biomass is made up of trees less than 5 inches d.b.h., 18 percent is made up of trees 5.0-6.9 inches d.b.h., and 19 percent is made up of trees 7.0-8.9 inches d.b.h. (table 3).

**MINNESOTA'S ASPEN RESOURCE**

GOVT. DOCUMENTS  
 DEPOSITORY ITEM

JUN 8 1981

CLEMSON  
 LIBRARY

**Pamela J. Jakes**  
 Associate Resource Analyst

**ABSTRACT.**—The fourth Minnesota Forest Inventory shows that aspen continues to dominate the State's forests. Thirty-nine percent of Minnesota's commercial forest area is in the aspen forest type. Aspen species accounted for the largest portion of growing-stock inventory, net annual growth, and removals.

**KEY WORDS:** Forest survey, forest area, timber volume, removals, growth.

The fourth Minnesota Forest Inventory shows that aspen continues to dominate the State's forests. In 1977, the aspen forest type covered 5.3 million acres of commercial forest land—39 percent of the total commercial forest area in Minnesota. Although the total aspen area in the State declined slightly between inventories, the area of aspen in north-central Minnesota increased (table 1).

Farmers own nearly one-quarter of the State's aspen (table 2). County and municipal agencies and miscellaneous private owners hold another large block of the aspen resource.

Most of Minnesota's aspen area is in poletimber stands; only 15 percent of the aspen stands are sawtimber (table 3). Twenty-eight percent of the commercial forest area in other forest types is in sawtimber stands.

Aspen stands are younger, on average, than stands of all other forest types. Seventy-two percent of the aspen forest type acreage is less than 51 years old; only 47 percent of the stands in forest types other than aspen are less than 51 years old (fig. 1).

| All classes          | 13,695.1  | 5,302.3    | 8,392.8     |

Aspen volume in Minnesota totaled 4.0 billion cubic feet in 1977. Most of this volume is in growing-stock trees (table 4).

As aspen stands matured, growing-stock volume increased from 2.8 billion cubic feet in 1962 to 3.4 billion cubic feet in 1977. Aspen growing-stock volume per acre increases steadily to age 70, then levels off (fig. 2).

The northern two Forest Survey Units account for 89 percent of the aspen growing-stock volume (fig. 3). Except for Pine County, no county outside the Aspen-Birch and Northern Pine Survey Units has more than 36 million cubic feet of aspen.

Some aspen occurs in all forest types in Minnesota showing that management of other forest types can also yield aspen volumes (table 5).

Table 4.—Net volume of aspen by species class and tree class, Minnesota, 1977  
(In thousand cubic feet)

| Species class   | All live   | Growing stock | Cull trees |                  |
|-----------------|------------|---------------|------------|------------------|
|                 |            |               | Short-log  | Rough and rotten |
| Total softwoods | 3,682,926  | 3,477,007     | 27,060     | 178,859          |
| Hardwoods:      |            |               |            |                  |
| Quaking aspen   | 3,782,905  | 3,236,405     | 60,256     | 486,244          |
| Bigtooth aspen  | 201,225    | 174,315       | 3,398      | 23,512           |
| Aspen subtotal  | 3,984,130  | 3,410,720     | 63,654     | 509,756          |
| Other hardwoods | 5,178,774  | 4,566,270     | 93,743     | 518,761          |
| Total           | 9,162,904  | 7,976,990     | 157,397    | 1,028,517        |
| All species     | 12,845,830 | 11,453,997    | 184,457    | 1,207,376        |

Although cubic feet of growing-stock is a traditional measure of tree volume, the tree biomass on commercial forest land outside the national forests was estimated during the fourth Minnesota Forest Inventory. Tree biomass gives a more complete measure of volume, because it is the above-ground volume of all live trees from a 1-foot stump, including the bark. Biomass in aspen species totaled 163 million green tons in 1977 (table 6).

Net annual growth of quaking and bigtooth aspen growing-stock totaled 94 million cubic feet in 1976—2.8 percent of total aspen volume. In the aspen forest

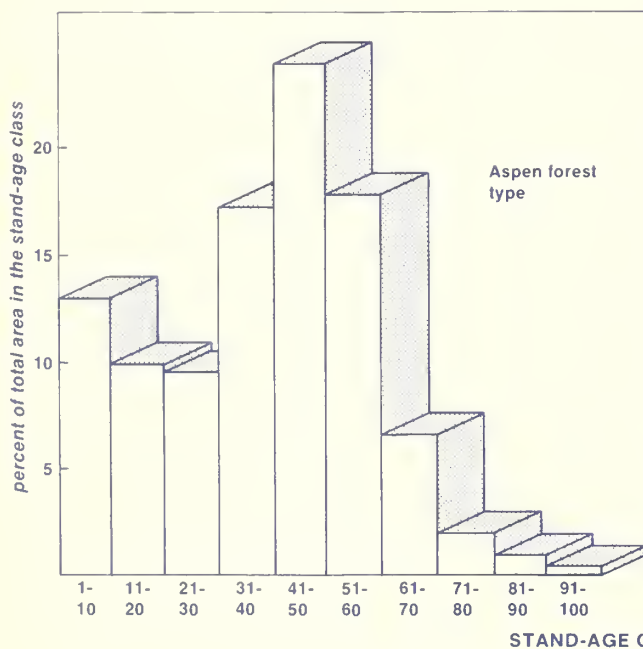

Figure 1.—Percent distribution of area among stand-age classes, aspen forest type, and all other forest types, Minnesota, 1977.

Figure 2.—Growing-stock volume per acre by stand-age class, aspen forest type, Minnesota, 1977.

type, growth totaled 153 million cubic feet, an average of 29 cubic feet per acre.

Although aspen growing-stock accounted for 27 percent of the total net annual growth in 1976, it made up 38 percent of growing-stock removals. In 1976, removals from aspen growing stock totaled 73 million cubic feet, up 60 percent from the 46 million cubic feet removed in 1962. More than half the aspen removals (43 million cubic feet) went to pulpwood (table 7). Other removals and logging residue accounted for another 20 percent of the total aspen removals. Other removals are growing-stock trees felled but not used for products, or trees left standing but "removed" from the commercial forest land base by land-use change. Such removals include those resulting from timber stand improvement, land clearing, and other management activities.

Aspen mortality in Minnesota in 1976 was 71 million cubic feet. More than 63 percent of the aspen mortality was caused by disease:

| Cause             | Aspen mortality<br>(Thousand cubic feet) |
|-------------------|--|
| Insects           | 612                                      |

**ABSTRACT.**—The original site index curves for balsam fir and white spruce are revised from a breast height age to a total age basis. Site index values from these revised curves are thus comparable to site index values for other species that are based upon total tree age. This note also includes formulations for estimating site index by using computers or programmable, hand-held calculators.

**KEY WORDS:** total age revisions; site index formulation.

Harmonized site index curves have been published for balsam fir (*Abies balsamea* (L.) Mill.) and white spruce (*Picea glauca* (Moench) Voss) in the Lake States (Gevorkiantz 1956, 1957). These curves define site index as the height of dominant and codominant trees at breast-height-index age of 50 years. In contrast, the index age for most standard site index curves is total tree age at 50 years. Basing site index on breast height age avoids including much of the erratic initial height growth of trees that may suffer from early suppression, frost damage, or animal and insect injury. However, site index values estimated from curves based on breast height age cannot be directly compared to those estimated from site curves based on total tree age.

Our site index curves (figs. 1 and 2) for balsam fir and white spruce are adopted from the original Gevorkiantz harmonized site index curves. We have

merely redrafted the original curves by converting them from breast height age to total tree age. Therefore, the revised site index curves have the shortcomings of the original harmonized curves.

These revised curves can be used in the field for directly estimating site index. But this process is slow and tedious, particularly when site indices are estimated from many trees such as in forest surveys or in timber management plans. Moreover, such site index estimates may be subject to error when interpolations are made between the site curves on the site index graphs. Therefore, we include height growth and site index equations that can be used with programmable, hand-held calculators or with programs written for digital computers.

### METHODS

Unfortunately, the amount and kind of data and the statistical procedures used for the original curves are not well described by Gevorkiantz (1956, 1957). Data were probably total height and age values measured from dominant and codominant trees on forest survey and yield plots. These height and age data probably were then used for calculating average height-age guiding curves from which a family of proportional harmonized site index curves were constructed.

Using each of Gevorkiantz's site index curves, we read total tree height values for each 10-year breast height age. Then we added a number of years to breast height age to obtain total tree age, the number depending on site class:<sup>1</sup>

|                  |    |    |    |    |    |    |
|------------------|----|----|----|----|----|----|
| Site Index Class | 30 | 40 | 50 | 60 | 70 | 80 |
| Years added      | 15 | 13 | 11 | 10 | 9  | 8  |

The total age and total height values for each site class were then used to plot height-age curves. Proportional methods were used to adjust these plotted curves so that at a total age of 50 years the tree heights conformed exactly with the 50-year height specified for each site index class (figs. 1 and 2).

The values used for plotting the revised site index curves were next used for computing height growth equations that describe the revised curves. We also computed site index prediction equations. The equation models we used are:

$$H = b_1 S^{b_2} (1 - e^{-b_3 A})^{b_4} S^{b_5} \quad (1)$$

$$S = b_1 H^{b_2} (1 - e^{-b_3 A})^{b_4} H^{b_5} \quad (2)$$

where H = Total height of dominant and codominant trees in feet

S = Site index (total height of dominant and codominant trees at 50 years total age)

A = Total age in years

e = Base of the natural logarithms

b<sub>1</sub> .. b<sub>5</sub> = Parameters to be estimated, using weighted nonlinear least squares regression.

Parameters for balsam fir and white spruce are:

| Species          | b <sub>1</sub> | b <sub>2</sub> | b <sub>3</sub> | b <sub>4</sub> | b <sub>5</sub> | R <sup>2</sup> | SE   | Bias<br>(Percent) |
|------------------|----------------|----------------|----------------|----------------|----------------|----------------|------|-------------------|
| Balsam fir H =   | 2.0901         | 0.9296         | -0.0280        | 2.8280         | -0.1403        | 0.99           | 0.54 | 0.01              |
| Balsam fir S =   | 0.2198         | 1.1644         | -0.0110        | -2.0364        | -0.1775        | 0.99           | 1.10 | -1.17             |
| White spruce H = | 10.8738        | 0.5529         | -0.0343        | 34.6880        | -0.6139        | 0.99           | 2.33 | -0.27             |
| White spruce S = | 0.0833         | 1.3965         | -0.0196        | -8.0895        | -0.3659        | 0.98           | 3.22 | 2.11              |

## DISCUSSION

Because these revised site index curves are based only on the original curves calculated by Gevorkiantz, they have the same errors and disadvantages of the original harmonized site index curves. New site curves based on stem analysis methods are recommended for balsam fir and white spruce in the Lake States.

When height growth and site index equations are used with a programmable calculator, the parameters and a simple program for solving the equation are entered and then stored. The estimates of site index are obtained by manually entering the species code and values for total height and total age.

The standard precautions in using site index curves also apply in using these equations for site index: site trees should be at least 20 years old and should be free growing, uninjured, dominant and codominant trees. Such trees commonly occur in well stocked, even-aged stands that have not been disturbed by past cutting. We recommend that increment cores for tree age be taken at breast height. Breast height age and total height values should then be compared to the site index curves for an estimate of the general site class. Next d.b.h. age should be converted to total age by using the number of years listed for each site class (figs. 1 and 2). These total age and total height values are then used for graphically estimating site index from the curves or for estimating site index using the formulae.

<sup>1</sup>These assumed years are currently used by the forest survey crews of the USDA Forest Service. Because the accuracy of these assumptions is unknown, much error in estimating both total age and site index can occur if trees initially grow faster or slower in height than assumed.

Figure 1.—Site index curves for balsam fir in the Lake States. These are revised from the original curves published by Gevorkiantz (1956). Add the appropriate number of years from table 1 to breast height age to obtain total age.

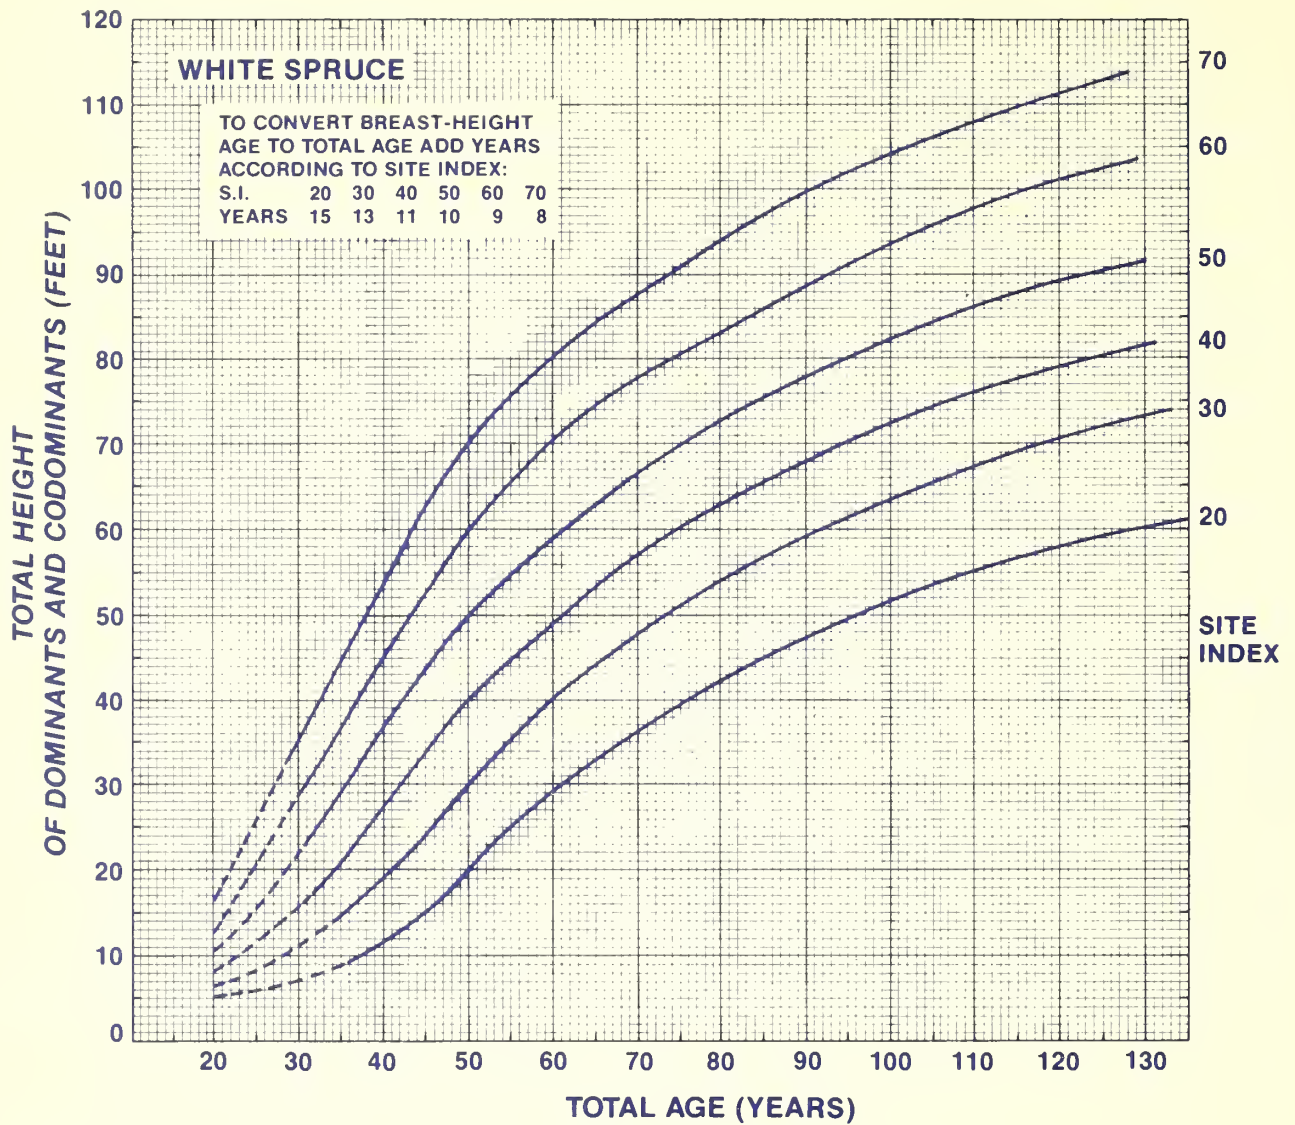

Figure 2.—Site index curves for white spruce in the Lake States. These are revised from the original curves published by Gevorkiantz (1957). Add the appropriate number of years from table 1 to breast height to obtain total age.

**ABSTRACT.**—An efficient Ceramic-Cup Water Collection Instrument (CCWCI, "quickie") is described. Soil water collection from ceramic-cup samplers may require compositing by equal volume from distantly spaced samplers, or simultaneous water collection from closely spaced samplers without compositing. All collection must be done with minimal opportunity for sample contamination. The CCWCI combines these and other soil water collection needs into a streamlined system that may be adapted to a variety of experimental designs and field conditions.

**KEY WORDS:** porous cups, soil solution, soil leachate, ceramic-cup lysimeters, nutrients.

Porous ceramic-cup samplers are widely used in soil nutrient studies to extract soil water from various soil depths. Under vacuum, these samplers draw water from the soil and temporarily store it. Then, the stored water must be collected and transported to a laboratory for chemical analysis. Unfortunately, there are no collection instruments commercially available for this time-consuming and repetitive procedure. To fill that gap, we have developed a Ceramic-Cup Water Collection Instrument (CCWCI, pronounced "quickie"). The CCWCI is well suited to studies with many ceramic-cup samplers that require sample collection at frequent intervals or require sample compositing in the manner suggested by Hansen and Harris (1975).

The basic features of CCWCI are:

1. It permits compositing by equal volumes from widely spaced samplers.

2. It permits simultaneous sample collection from several samplers located adjacent to each other.
3. It retains a vacuum while being moved from one subsampling point to the next, thereby minimizing the vacuum pumping operation.
4. It permits the reapplication of a vacuum to the samplers in one continuous operation with sample collection.
5. It minimizes sample contamination from outside sources.
6. It permits splitting of composited samples into two or more sample storage containers.
7. It has space for carrying sample storage pacs and sampler repair materials.
8. It is fabricated from lightweight commonly available materials using conventional shop tools.
9. It may be modified to meet the needs of different sampling schemes.
10. It is intended for use with two-line porous ceramic-cup samplers similar to those described by Linden (1977), and Knighton and Streblov (1981).

### MATERIALS

The CCWCI system described here (fig. 1) is designed to collect subsamples at two soil depths at each of two widely spaced subsampling points. The materials required are:

| Material  | Quantity   | Cost     |
|---|--|----------|
| Available through Curtin Matheson: <sup>1</sup>   |  |          |
| Tubing, latex 5 mm ( $\frac{3}{16}$ in.) I.D.<br>Cat. No. 244-491   | 203 cm (80 in.)  | \$ 1.75  |
| Tubing, latex, 6 mm I.D. $\times$ 16 mm<br>O.D. ( $\frac{1}{4}$ in. $\times$ $\frac{5}{8}$ in.)<br>Cat. No. 203-471 | 30.5 cm (12 in.)   | .90      |
| Tubing, polyethylene 3 mm ( $\frac{1}{8}$ in.)<br>I.D.<br>Cat. No. 204-875  | 203 cm (80 in.)  | 1.75     |
| Available through Plasticware catalog: <sup>2</sup>   |  |          |
| Desiccator, vacuum 171 mm (6 in.)<br>Cat. No. 6514-10   | 1 each   | 27.00    |
| Available through Chemical Lab:   |  |          |
| Clamps, pinchcock   | 10 each  | 6.00     |
| Flask, Erlenmeyer 500 ml heavy wall   | 4 each   | 7.04     |
| Stoppers, rubber #00 1-hole   | 2 each   | .20      |
| Stoppers, rubber #7 3-hole  | 4 each   | 1.68     |
| Y-connector, polypropylene 6 mm ( $\frac{1}{4}$ in.)  | 2 each   | .36      |
| Available through most local hardware stores:   |  |          |
| Aluminum sheet 24 gauge   | 16.5 cm $\times$ 28 cm<br>(6- $\frac{1}{2}$ in. $\times$ 11 in.)             | 1.25     |
| Angle aluminum 19 mm $\times$ 2 mm ( $\frac{3}{4}$ in. $\times$ $\frac{1}{16}$ in.)                                 | 5.34 m (17 ft 6 in.)   | 8.40     |
| Bolts, flat or round head, 5 mm $\times$ 19 mm ( $\frac{3}{16}$ in. $\times$ $\frac{3}{4}$ in.)                     | 4 each   | .25      |
| Aluminum Rivet Back-up Plates 3 mm ( $\frac{1}{8}$ in.)   | 30 each  | 1.00     |
| Door pull handle 15 cm (6 in.)  | 1 each   | 1.50     |
| Hasp, draw pull 16 mm $\times$ 41 mm<br>( $\frac{5}{8}$ in. $\times$ 1- $\frac{5}{8}$ in.)                          | 1 each   | 1.10     |
| Hinge 2.5 cm $\times$ 2.5 cm<br>(1 in. $\times$ 1 in.)  | 7 each   | 3.25     |
| Hinge 3.8 cm $\times$ 3.8 cm<br>(1- $\frac{1}{2}$ in. $\times$ 1- $\frac{1}{2}$ in.)                                | 2 each   | 1.10     |
| Lid support   | 1 each   | 2.00     |
| Masonite, tempered 5 mm ( $\frac{1}{8}$ in.)  | 122 cm $\times$ 52 cm<br>(48 in. $\times$ 20- $\frac{1}{4}$ in.)             | 1.50     |
| Nuts, 5 mm ( $\frac{3}{16}$ in.) thread   | 4 each   | .15      |
| Plexiglass, clear, 3 mm ( $\frac{1}{8}$ in.)  | 23 cm $\times$ 51 cm<br>(9 in. $\times$ 20- $\frac{1}{8}$ in.)               | 4.00     |
| Plexiglass, clear, 6 mm ( $\frac{1}{4}$ in.)  | 25 cm $\times$ 25 cm<br>(9- $\frac{3}{4}$ in. $\times$ 9- $\frac{3}{4}$ in.) | 2.75     |
| Pop-rivets, aluminum  | 125 total  | 5.00     |
| 3 mm $\times$ 6 mm ( $\frac{1}{8}$ in. $\times$ $\frac{1}{4}$ in.),   |  |          |
| 3 mm $\times$ 9 mm ( $\frac{1}{8}$ in. $\times$ $\frac{3}{16}$ in.),  |  |          |
| 3 mm $\times$ 12 mm ( $\frac{1}{8}$ in. $\times$ $\frac{1}{2}$ in.)   |  |          |
| Rubber band 3 mm $\times$ 15 cm<br>( $\frac{1}{4}$ in. $\times$ 6 in.)  | 1 each   | .15      |
| S-hooks, 25 mm (1 in.)  | 2 each   | .34      |
| Strap aluminum, 13 mm $\times$ 3 mm<br>( $\frac{1}{2}$ in. $\times$ $\frac{1}{8}$ in.)                              | 35.5 cm (14 in.)   | .66      |
| Tape  |  |          |
| Velcro, 19 mm $\times$ 3 mm<br>( $\frac{3}{4}$ in. $\times$ $\frac{1}{8}$ in.)                                      | 61 cm (24 in.)   | 4.00     |

Houston, Texas 77001.

<sup>2</sup>Plasticware catalog, Cole-Parmer Instrument Co.,  
7425 North Oak Park Ave., Chicago, Illinois 60648.

An experienced craftsman can fabricate one CCWCI  
in 30 working hours.

there are four ceramic-cup samplers per plot with one deep and one shallow sampler at each of two widely spaced subsampling points. It is assumed the samples collected from the two shallow samplers are to be composited, as are the samples from the two deep samplers.

1. At one pair of samplers, attach the shallow sampler collection line to the right front CCWCI sample collection line and similarly attach the deep sampler to the left front CCWCI sample collection line.
2. Release the clamps on the two front vacuum-overflow lines attached to the samplers.
3. Attach a vacuum pump to the vacuum line on the overflow reservoir.<sup>3</sup>
4. Release the clamp on the vacuum line and draw a vacuum. Water will be drawn from the samplers into the flasks. The flask will retain approximately 400 ml and the excess will be drawn into the overflow reservoir.
5. Be prepared to place a clamp on each air inlet line of the ceramic samplers immediately when it is visibly, or audibly evident air is being drawn into the attached flask which indicates the sampler is empty.
6. After both samplers are empty, continue to draw a vacuum until the entire system is recharged to the desired vacuum.
7. Place clamps on the ceramic sampler lines, on the vacuum-overflow lines, and on the vacuum pump line.
8. Disconnect the samplers, attach the sampler line ends together, and remove the two clamps. The vacuum will be lost in the flasks but not in the overflow reservoir.
9. Disconnect the pump, move to the next pair of samplers, and repeat steps 1 to 8 using the back flasks and matching the shallow and deep samplers on the same sides of the CCWCI used at the previous subsampling point.
10. Composite the two deep samples and the two shallow samples. Do this by drawing the two drain lines out through the CCWCI side access

door and draining an equal sample volume from each flask into a sample container. If the composited sample must be split into different containers to meet analytical requirements, do this by draining visually estimated equal volumes into each container.<sup>4</sup>

11. Drain excess sample water out of the flasks. It is not normally necessary to flush the CCWCI between samples because the dilution effect is overwhelming. However, flushing with distilled water may be necessary if extreme differences in element concentrations are expected.
12. Remove the bottom of the overflow reservoir and discard overflow water only when necessary because this destroys the vacuum in the CCWCI.
13. Move to the next plot and repeat the procedure.

<sup>3</sup>*Either a large-volume pump equivalent to the Boekel 2043 (Curtin Matheson Scientific, Inc., Cat. No. 196-758) equipped with a vacuum gauge or a smaller pump equivalent to the Pressure-Vacuum Hand Pump (Cat. No. 2001) from Soilmoisture Equipment Corp., P.O. Box 30025, Santa Barbara, California 93105.*

<sup>4</sup>*Plastic 6-oz. Whirl-pac bags (Curtin Matheson Scientific, Inc., Cat. No. 205-070) are convenient for sample collection and storage.*

Modify the desiccator to serve as a vacuum and water overflow reservoir. Drill two holes, 1.2 cm in diameter, in opposite sides of the lid. Center them 2 cm from the knob. Place the desiccator base in the hole provided in the bottom panel of the CCWCI. Attach tubing compatible with the vacuum pump to the existing vacuum port on the side of the desiccator lid. Position the lid on the desiccator base and extend the tubing about 5 cm to 6 cm out of the hole in the plexiglass front. Secure the desiccator to the CCWCI by stretching a large rubber band from the side panel hooks across the desiccator lid. Insert the "Y's" into No. 00 1-hole rubber stoppers and set the stoppers in the drilled holes in the desiccator lid.

Invert four Erlenmeyer flasks in the flask support, and attach tubing to each housing using a 3-hole No. 7 rubber stopper as follows:

1. Sample collection line—use polyethylene tubing from 18 cm beyond the inside stopper surface through the stopper to just inside the closest CCWCI side panel sample collection line hole

**SIDE VIEW**

Figure 3.—Side view of the completed CCWCI.

which is 1 cm in diameter. Use 10 cm of latex tubing to extend this line through the hole.

2. Vacuum-overflow line—use polyethylene tubing from 16 cm beyond the inside stopper surface to 2 cm beyond the outside stopper surface. Use latex tubing to extend this line to a "Y" on the overflow reservoir (desiccator) lid.
3. Drain line—use polyethylene tubing from flush with the inside of the stopper to 2 cm outside. Use 20 cm of latex tubing beyond this and dangle it from the stopper.

Once the lines are installed securely, tape the stoppers to the flask. Attach pinchcock clamps to each drain line and to each overflow line. The completed CCWCI is illustrated in figure 4 with two models of ceramic-cup samplers and a small hand-held vacuum pump.

## OPERATION

Many variations exist for collecting individual or composite samples. The following steps describe the procedure for field operation of the CCWCI when

Figure 4.—Completed CCWCI with ceramic soil water samplers and small hand-held vacuum pump.

## FABRICATION

Construct a box (fig. 1) to contain the CCWCI sample collection equipment. Use angle-aluminum for the frame; use masonite for the bottom, flask-support, sides, and back panels; and use plexiglass for the front and top panels. Use pop rivets with backup plates as fasteners. Details and dimensions are illustrated in figures 2 and 3.

Assemble the outside angle-aluminum frame first. The inside flask-support frame should not be cut or installed until the side panels have been placed in the frame. Cut the bottom, front, side and back panels to inside frame dimensions. Use two layers of masonite for the bottom panel and cut a hole 10.3 cm in diameter in the upper layer to hold the bottom of the overflow reservoir when it is in place. Cut access doors 17 cm<sup>2</sup> in each masonite side panel as indicated (fig. 3). The doors should be located so that they close against the angle-aluminum frame of the flask-support. Glue strips of Velcro to the leading edge of each door and to the aluminum doorstop to hold the doors closed. Cut an access door in the back panel just above the lower angle-aluminum frame 19 cm wide

Figure 1.—Front view of the empty CCWCI box.

and at least 24 cm long. An aluminum bar must be installed inside the upper edge of the door opening to serve as a doorstop. Use Velcro strips to hold the door closed. Fingerholes, 2 cm in diameter, should be drilled near the leading edge of each door for easy opening. Drill two holes 6 mm in diameter in each side panel as indicated for sample collection lines. Storage pockets may be attached inside each side panel beneath the access doors using sheet-aluminum folded to desired dimensions. We use the pockets to hold whirl-pac sample storage bags that are pre-labeled and may have sample preservative added in advance. Drill one hole in the front panel for a vacuum line. After the panels are secured in the aluminum frame, the flask-support frame and panel may be cut to inside dimension of the box and assembled. Cut a hole 7.8 cm in diameter in the center of each quadrant of the flask-support panel to hold inverted Erlenmeyer flasks. Cut the CCWCI plexiglass lid and fasten a strip of angle-aluminum along the leading edge (fig. 3) and attach the clasp loop to the aluminum. Also, attach a carrying handle and a support bracket to the lid.

## INSOLATION AT CARTERVILLE, ILLINOIS

Peter Y. S. Chen, *Forest Products Technologist,*  
*Carbondale, Illinois*

GOVT. DOCUMENTS  
DEPOSITORY ITEM

JUL 22 1981

CLEMSON  
LIBRARY

**ABSTRACT.**— Insolation measured with a precision spectral pyranometer, was recorded near Carterville, Illinois, for 1 year. The pyranometer was tilted at an angle of 25° in summer, 50° in winter, and 37.5° in spring and fall. The insolation measured in winter was found to be significantly larger than the insolation estimated on a horizontal surface.

**KEY WORDS:** Pyranometer, tilting, horizontal surface, beam radiation, reflected radiation.

A better understanding of insolation, the total solar radiation, throughout the year is needed to evaluate the efficiencies of the solar collectors and solar kilns used in hardwood drying research. So insolation has been measured daily with a pyranometer at the North Central Forest Experiment Station's Wood Processing Pilot Plant near Carterville, Illinois (37.5° N), since the fall of 1978. This precision spectral pyranometer was considered more sensitive, precise, durable, and rapid in response than other types of instruments that measure total solar radiation. It was mounted on top of a solar collector (fig. 1) that was tilted at an angle of 25° in summer, 50° in winter, and 37.5° in spring and fall to increase the reception of solar radiation. Daily insolation was recorded automatically on strip charts by a dual pen recorder with an electronic integrator. The upper pen traces the instantaneous values of insolation (peaks), while the lower pen produces an oscillatory trace, or integration, on a marginal scale to provide a count of the area under the peaks traced simultaneously by the upper pen.

## RESULTS

Mean daily insolation, with standard deviation, was calculated for each month in 1979; maximum and minimum daily insolation was also noted. Insolation peaked during June and reached the lowest level during November (fig. 2). Amplitude, the range between maximum and minimum daily insolation, was greatest in February and the mean daily insolation was low; amplitude was least in July and the mean daily insolation was high. This is contrary to observations in West Virginia over a longer period of time (Patric and Caruso 1979).

The insolation measured in winter was significantly larger than the insolation estimated on a horizontal surface (table 1) (U.S. Department of Commerce 1968). Tilting the pyranometer to a 50° inclination probably caused the measured insolation to increase in winter. The pyranometer received not only more beam radiation (direct from the sun) but also more reflected radiation due to the snow-covered ground, especially during January and February (table 1).

To determine the solar collector size necessary to supply a certain portion of the heating requirement, one should consider the average daily temperatures of different months and seasons as well as the insolation (table 1). The ambient temperature does affect the efficiency of solar collectors.

Figure 1.—The precision spectral pyranometer mounted on top of a solar collector at the Wood Processing Pilot Plant near Carterville, Illinois (37.5° N).

# ESTIMATING TOTAL-TREE HEIGHT FOR UPLAND OAKS AND HICKORIES IN SOUTHERN ILLINOIS

Charles Myers,  
*Research Forester,*  
 and David M. Belcher,  
*Biometrician*

GOVT. DOCUMENTS  
 DEPOSITORY ITEM

JUL 20 1981

CLEMSON  
 LIBRARY

**ABSTRACT.**—An equation to predict total-tree height from merchantable length was developed for hardwoods:  $\hat{Y} = 30.0 + 0.85 X$ , with  $R^2=0.87$ .

**KEY WORDS:** Regression, merchantable height, Lake States, hardwoods.

Total-tree height is often used for determining weight or volume of standing trees. It is difficult to measure in hardwoods due to the lack of visibility and a well defined terminal. In this paper we examine relations between total-tree height and more easily measured variables. We find that total height can be estimated from merchantable height.

Data for this study came from measurements on 155 felled trees in the Shawnee National Forest in southern Illinois. Trees were selected from three 25-acre blocks on upland oak-hickory sites. The aspect was predominantly southern and the trees were dispersed from top to bottom of the slope. Trees were selected to give a representative range of size classes for each species. Species included are red oak, white oak, black oak, and hickories. Measured variables were:

**D.B.H.**—tree diameter at 4.5 feet above ground, on the uphill side of the tree;

**Merchantable length**—distance above 1-foot stump to a point on the main stem where diameter outside bark is 5 inches;

**Total height**—height above ground to the tip of the tree. Averages and ranges for these variables are:

| Variable                   | Average | Range     |
|----------------------------|---------|-----------|
| D.b.h. (inches)            | 13.5    | 5.0-23.6  |
| Merchantable length (feet) | 50.8    | 8.5-78.5  |
| Total height (feet)        | 73.2    | 37.5-96.6 |

A more complete display of the data (table 1), shows trends between the variables and the little variation in total height within a given merchantable height class.

After examining various plots of the data and screening several equation forms, we decided that a simple linear regression relating total-tree height to merchantable height was the best relation ( $Y = 30.0 + 0.85x$ , with  $R^2=0.87$ ). Gevorkiantz and Olson (1955) present total height as a function of merchantable height and d.b.h. for Lake States species. But we found that including d.b.h. did not appreciably improve our equation for southern Illinois trees (increased  $R^2$  by .003).

Total-tree height can be estimated from merchantable length measurements for selected hardwoods in southern Illinois by using the equation, graph or table (fig. 1, table 1). When merchantable

length is estimated as number of 8-foot bolts, use this tabulation:

| Merchantable length<br>(No. 8-ft. bolts) | Total height<br>(Feet) |
|--|------------------------|
| 1  | 37                     |
| 2  | 44                     |
| 3  | 50                     |
| 4  | 57                     |
| 5  | 64                     |
| 6  | 71                     |
| 7  | 78                     |
| 8  | 84                     |
| 9  | 91                     |

These results essentially agree with those of Gevorkiantz and Olson (1955) but give a simplified procedure and equation for obtaining total-tree height. Our data points and resulting equation approximate the diagonal of the Gevorkiantz and Olson table of total height by d.b.h. and merchantable height.

Because our results are essentially the same as those of Gevorkiantz and Olson, their tables should apply in southern Illinois and our equation and tables should apply in the Lake States. But bottom-land hardwoods, particularly eastern cottonwood, might require a different equation or table.

*Principal Forest Hydrologist,  
Grand Rapids, Minnesota*

**ABSTRACT.**—Measurements of lake and impoundment pH for several years, intensive sampling within years, and pH-calcium plots verify normal pH levels and do not show evidence of changes due to acid precipitation. These data in comparison with general lake data narrow the northern Lake States area in which rain or snow may cause lake acidification.

**KEY WORDS:** Acid rain, acid precipitation, limnology, lake pH.

Acidity has increased in poorly buffered lakes of southern Scandinavia and eastern North America during the last 30 to 40 years (Wright and Gjessing 1976). Acid precipitation is thought to be the cause. It has spread in North America in recent decades (Likens *et al.* 1979), and lakes and streams in some watersheds with low buffering capacity are becoming more acid as a result (Jeffries *et al.* 1979, Henriksen 1979). We studied pH changes in lakes and impoundments in north-central Minnesota to see if lakes in this area showed signs of acidification due to acid precipitation.

## METHODS

In the spring of 1974, we measured surface water pH and specific conductance (corrected to 25°C) in 17 lakes near the Marcell Experimental Forest in north-central Minnesota (fig. 1). We used this information in combination with water table maps to classify the lakes as perched, transitional, or strongly groundwater-fed (Hawkinson and Verry 1975). We remeasured these

lakes in the fall of 1979 and measured four additional lakes in the same area. In the spring of 1980 we again measured pH and conductance in all 21 lakes and analyzed the water for calcium using atomic absorption (Perkin-Elmer 1973) and apparent color using a <sup>1</sup>Hellige Aqua Testor<sup>TM</sup> with colored glass discs calibrated to platinum-cobalt standards such that one color unit equals 1 mg Pt/l. True color was determined the same way after passing the water through a 0.45 μm filter. Lake samples were taken by gently lowering a glass beaker into the surface water of the littoral. Acidity (pH) and conductance were measured immediately with field-calibrated instruments and these values were checked the same or following day with laboratory meters. Lakes were in a mixed condition when all samples were taken. Changes in pH (calculations done with hydrogen ion activities) between the three measurement dates were tested for statistical significance at the 5 percent level of confidence using a paired t-test.

Seven shallow waterfowl impoundments in the Chippewa National Forest were measured for pH for 4 years (from April 1975 to May 1979) at least every 2 to 4 weeks throughout the year. One deep water marsh (Goose "Lake") in the Chippewa National Forest was similarly measured for 3 years (from March 1976 to May 1979).

In the spring of 1980, pH and calcium data for some of the 21 lakes were plotted and compared with Henriksen's lake acidification curve.

<sup>1</sup>Mention of trade names does not constitute endorsement of the products by the USDA Forest Service.

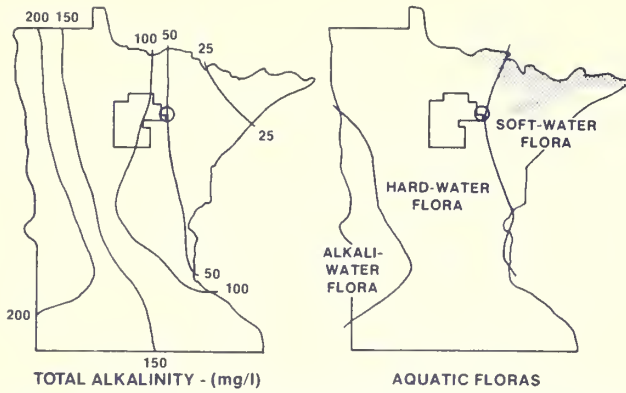

Figure 1.—Location of sample lakes, Marcell Experimental Forest (circle), and impoundments, Chipewewa National Forest (rectangle) in relation to Moyle's (1954) general lake data. Shaded area is exposed formation of Precambrian igneous and metamorphic rocks. These formations extend across the northern half of Minnesota to the Red River Valley but are generally covered with glacial drift.

## RESULTS AND DISCUSSION

Perched lakes in 1980 were 0.3 pH unit higher than in either 1974 or 1979 (table 1). Groundwater lakes were 0.2 pH unit lower in 1979 and 0.6 pH unit lower in 1980 than in 1974. Transitional lakes and data from other years for perched and groundwater lakes showed no statistically significant changes.

The most significant conclusion associated with these lake pH data is that no lake had a pH value below 6.0. Fish are not adversely affected at pH 6.0 and above. Thus, none of these lakes can be considered abnormally acidic. Even though some lake categories showed a statistical change in pH, it is presumptive to conclude that these changes represent a trend because lakes and impoundments normally vary approximately 1 pH unit annually.

The pH of the impoundments we studied ranged from 0.9 to 1.9 units annually (table 2). Such ranges in annual lake pH are also common. Lohammar (1938) measured lake pH at 70 sites in Sweden 3 or 4 times a year in 1933, 1934, and 1937 and found an average range of 0.9 pH units with ranges for individual lakes from 0.2 to 2.6 units. Juday *et al.* (1935) found a range in pH up to 1.4 pH units for 222 lakes measured for a period of 2 to 6 years (from 1925 to 1932) in northeastern Wisconsin and ranges up to 2.5 units in 23 additional lakes. Thus, interpretation of long-term lake pH changes from small sample numbers per year is difficult in light of normal

within-year variation. Intensive sampling throughout the year on selected lakes would establish a pH record over several years and would be more easily interpreted.

The pH of snow at the Marcell Experimental Forest ranges from 3.5 to 4.9. Jeffries *et al.* (1979) suggested that stream or lake water may approach these values during and after snowmelt and thus watersheds that are not able to buffer acid snowmelt would be identified.

Impoundment water pH does not show a depression to near snow pH values, but ranges from 5.7 to 7.7 during and after snowmelt (fig. 2). The impoundments we studied covered a range of water quality conditions. Ketchum impoundment is strongly fed by groundwater springs and has abundant water and an average specific conductance of 350  $\mu$ mhos. Bear Brook has a large organic soil surface watershed but significant amounts of groundwater inflow and an average specific conductance of 190. Cuba impoundment has a small watershed and is totally fed by surface water. It has an average specific conductance of 65. Water supply is not dependable and the impoundment nearly dried up during 1976 and 1977—two severe drought years. The pH of snow may not affect impoundment or lake pH if the snowpack is small. Snow water contents at maximum pack average 13 cm; only 1977 had a small snowpack: 1975, 20 cm; 1976, 13 cm; 1977, 4 cm; 1978, 11 cm; and 1979, 18 cm.

Acidity (pH) of the impoundments is least variable during February and March and generally low at this time. These under-ice values may result from respiration-generated carbon dioxide. Ice-out on these impoundments generally occurs during the third week of April—about 1 to 1½ weeks after snow has

Figure 2.—pH (25°C) of three impoundments on the Chipewewa National Forest.

<sup>1</sup>pH data were excluded in naturally dry or purposefully drawn-down impoundments.

melted from the uplands. pH varies more in April than under the ice, but generally tends to rise. Thus, these water bodies do not experience a low pH, snowmelt shock as experienced in other areas.

We plotted pH over calcium concentration for 15 lakes and compared these with an empirical curve developed by Henriksen (1979) to show lakes that may be losing bicarbonate ions due to acid precipitation but have not changed greatly in pH. Henriksen's empirical curve was developed with calcium concentrations up to 6 mg/l. Thus six of the lakes we studied are not shown because their calcium concentrations are greater than 10 mg/l (table 1). All but 1 of the 15 lakes plotted well below the empirical line separating lakes that are losing bicarbonate from those that are not (fig. 3). The single point above the line (indicating acidification) represents Shorty's Lake, which receives naturally low pH, highly colored water from surrounding organic soils (table 2). In Henriksen's (1979) words, "When applied to data from such waters (highly colored), the indicator (line) implies an apparent acidification where none has occurred."

A broader interpretation of these data can be made by reference to figure 1 showing Moyle's (1954) areas of alkalinity and hard water-soft water flora in Minnesota. It is unlikely that lakes to the west of the hard water-soft water line or west of the 50 mg/l CaCO<sub>3</sub> line will be changed by acid precipitation because of sufficient buffering capacity in watershed soils and groundwater aquifers. Interpretations of the acidification impact on lakes to the east of these lines need further analysis. It is known that lakes in northeastern Wisconsin have had pH values as low as 4.4 since 1925 when they were first measured (Juday *et al.* 1935). Some of these lakes have color values as low as 16. Thus, interpretations in soft water lakes with low pH values are difficult and should be done with intimate knowledge of the lake, its watershed, and hydrology. General surveys such as Moyle's help us sharpen our perspective.

The data in this paper establish a pH record for some lakes and impoundments in north-central Minnesota. Precipitation in this area is acid—listed snow pH values range from 3.5 to 4.9 and rain pH values range from 3.6 to 6.5. However, lakes and impoundments in this area exhibit normal pH values and do not show evidence of becoming more acidic.

**ABSTRACT.**— Reports development and use of a radio transmitter device that can be dropped from aircraft into target areas in remote habitats. Such a device could be a valuable tool for studying and managing forests and wildlife, for controlling forest fires, and for handling emergencies.

**KEY WORDS:** Wildlife, forest fire control, telemetry, forest research and management, disease and insect detection.

A radio transmitter that can be dropped from an aircraft for locating pockets of diseased trees in remote areas has been needed for some time. Pockets of diseased trees are often easily seen from the air, but are sometimes difficult to find on the ground because of the characteristics of certain diseases, the density of trees and shrubs, the number of trees affected, and the lack of ground reference points. Locations have been marked by dropping toilet paper, plastic flagging, crepe paper, and aluminum foil, but none of these markers have been entirely satisfactory.

A radio transmitter, however, would enable forest managers to locate areas of diseased trees efficiently and quickly. It would expedite the harvesting of these trees before they are entirely dead and before the wood

becomes unusable. Using such a method, forest managers could more easily mark areas and check them on the ground for research or survey purposes. Electronic markers have been successfully used in Canada to locate small forest fires (Ponto and Lynch 1973).

We carried out a study to develop and test radio transmitter packages that could be safely dropped from an aircraft into designated areas, and to find out how quickly those transmitters could be found on the ground. For successful use, the transmitter had to meet four criteria: (1) it would not injure anyone it hit, (2) it would be protected upon impact, (3) it would accurately fall into the target area, and (4) it would emit a signal that could be detected with receivers from a distance of at least 2 miles on the ground and at least 10 miles from the air.

### MATERIALS AND METHODS

#### Tower Drops

Initial tests were made at the University of Minnesota radio-tracking facilities at the Cedar Creek Natural History Area, Bethel, Minnesota. Radio transmitters were placed in several devices, and each

device was dropped 12 times from a 100-foot tower. The following devices were tested:

- a. Army transmitter with steel point (15 inches long, 70.0 ounces).
- b. Plastic toy rocket (5 inches long, 0.35 ounce).
- c. Foam rubber Nerf<sup>1</sup> ball (7-inch diameter, 2.5 ounces with a 36-inch plastic flagging tail).
- d. Foam rubber Nerf ball (4-inch diameter, 0.5 ounce, with a 36-inch plastic flagging tail).
- e. Sponge (6.5 inches long, 2 inches wide, 1.8 ounces).
- f. Sponge-type football (5 inches long, 0.3 ounce).

Transmitters encapsulated in acrylic and weighing from 1.8 to 5.3 ounces were placed in the device. Each transmitter had a 12-inch antenna. Transmitter frequencies of 52.810 to 53.270 MHz and 150.700 to 151.275 MHz were used. An AVM<sup>1</sup> Model LA 12 receiver with a hand-held yagi antenna was used most of the time. Some tests were done with a receiver with a loop antenna (fig. 1).

Figure 1.—*Tuning radio receiver to transmitter frequency.*

## Aircraft Drops

The 7-inch foam rubber Nerf ball was used in all air drops because it met our four criteria during initial testing and because its bright orange color made it highly visible. A slit was made in the ball and the transmitter was inserted into the center of the ball so that it was completely protected (fig. 2). Plastic flagging was attached to the ball at the slit that was then sewn closed with a heavy thread. Drops were made from single-engine aircraft at altitudes ranging from 100 to 1,200 feet. The aircraft either flew a

Figure 2.—*Nerf ball radio transmitter package.*

straight approach or circled the target area at speeds ranging from 70 to 120 mph. Wind speeds ranged from 5 to 10 mph during drops. Twenty drops were made on 6 different dates into various habitats (table 1). Ground searches were conducted either the day of the drop, or 1 day or 5 days after. Distances from the nearest road to the transmitter ranged from 75 to 880 yards.

## RESULTS

All transmitter packages were recovered undamaged after being dropped by aircraft into different habitats (table 1). All were found on the ground except one that was lodged in a tree. Search times ranged from 5 to 40 minutes after a signal was received. Distances from roads, brush density, and snow depth influenced the amount of search time needed. In seven drops, the transmitter package was either partially or entirely below the snow surface, leaving only the bright flagging exposed. This added visibility was important in decreasing the time that it took to locate and retrieve the marker.

Search crews were able to find target areas in all but two of the drops: in one, the small target area was missed; in the other, the transmitter landed in a creek and floated downstream, out of the target area. To hit target areas, the drops had to be properly timed in relation to airspeed. Accuracy from higher altitudes was achieved when drops were made from an aircraft circling the target area. Larger target areas were marked using the straight-line approach. On one drop, the tail of the transmitter device became entangled with the antenna, apparently causing greater drift.

<sup>1</sup>Mention of trade names does not constitute endorsement of the products by the USDA Forest Service.

## **DISCUSSION AND CONCLUSIONS**

Because of its safety and effectiveness, the foam rubber ball transmitter package is more suitable than previous marking devices. Although fixed-winged aircraft were used in this study, we believe that using this device with helicopters would permit even more accurate marking of ground locations.

This technique can have many uses: to quickly locate pockets of diseased and dying trees such as those infected by dwarf mistletoe, oak wilt, Dutch elm disease or insect outbreaks in remote, roadless areas; to mark fires that produce little smoke and are

visible only from the air; to mark wolf-killed deer, wolf dens, large bird nests (e.g., goshawk, osprey, bald eagle), and other objects that are difficult to find from the ground; to speed recovery of lost or injured persons or to locate downed aircraft in remote areas.

## FOREST AREA IN NORTH DAKOTA, 1980<sup>1</sup>

Ronald L. Hackett  
*Mensurationist*

**ABSTRACT.**—In 1980 North Dakota's forest resources covered 518,100 acres of land, a slight decline from the 572,400 acres reported in 1954. The area of commercial forest land also dropped from 398,400 acres to 343,200 acres. The aspen forest type makes up 41 percent of the commercial forest area.

**KEY WORDS:** Commercial forest land, productive-reserved, unproductive, wooded strips, shelterbelts, nonforest with trees, forest type, land use.

One out of every 86 acres in North Dakota is forested—a total of 518,100 acres. Most forested acres occur along the Canadian border, along the valleys of the Red, Missouri, Little Missouri, and Sheyenne Rivers, and around Devils Lake (table 1). An area of 343,200 acres, or 66 percent of the total forest area, is suitable for producing industrial timber and is therefore classified as commercial forest land. The aspen forest type makes up 41 percent (139,500 acres) of the commercial forest area. The second largest forest type, elm-ash, accounts for 33 percent or 113,700 acres. The ponderosa pine forest type has the least area—1 percent or 2,100 acres:

| Forest type      | Area<br>(acres) |
|------------------|-----------------|
| Aspen            | 139,500         |
| Elm-ash          | 113,700         |
| Oak              | 44,200          |
| Cottonwood       | 18,700          |
| Plains hardwoods | 15,800          |
| Ponderosa pine   | 2,100           |
| Nonstocked       | 9,200           |
| Total            | 343,200         |

<sup>1</sup>The sampling error of area for this survey was +3.9 percent for the acres of commercial forest land.

The Eastern Unit of North Dakota is more heavily forested than the Western Unit (fig. 1). The most heavily forested County, Rolette, has 60,000 acres of commercial forest—10 percent of the land area (table 1).

Forest land declined in North Dakota by 53,900 acres or 9 percent between 1954 and 1980. Commercial forest land decreased 14 percent during the same period.

| Land Use      | 1954     | 1980     | Change since 1954 |         |
|---------------|----------|----------|-------------------|---------|
|               |          |          | Thousand acres    | Percent |
| Forest        |          |          |                   |         |
| Commercial    | 398.4    | 343.2    |                   | -14     |
| Noncommercial |          |          |                   |         |
| Unproductive  | 170.4    | 148.0    |                   | -13     |
| Reserved      | 3.2      | 26.9     |                   | +88     |
| Total forest  | 572.0    | 518.1    |                   | -9      |
| Nonforest     | 44,264.5 | 43,821.2 |                   | -1      |
| Total land    | 44,836.5 | 44,339.3 |                   | -1      |

Published 1954 areas have been adjusted to align the estimates more closely with definitions of land classification and procedures used in the 1980 survey.

Noncommercial forest land totals 174,900 acres. Since 1954, the reserved area has increased 741 percent or 26,900 acres (4,500 acres productive and 22,400 acres unproductive) primarily due to increases in the areas of State and national parks. The remaining 148,000 acres of unproductive forest land, too poor to grow timber products for industrial use, are concentrated in the Badlands area.

<sup>1</sup>/1970 Bureau of the Census estimates.

<sup>2</sup>/Land at least 16.7 percent stocked by forest trees of any size, or formerly having such tree cover, excludes land currently developed for nonforest use such as urban or heavily settled residential or resort area, city parks, orchards, improved roads or improved pasture land. The minimum forest area classified was 1 acre. Classified as forest were roadside, streamside, and shelterbelt strips of timber with a crown width of at least 120 feet and unimproved roads and trails, streams, and clearings in forested areas if less than 120 feet wide.

<sup>3</sup>/Land sufficiently productive to qualify as commercial forest land but withdrawn from timber utilization through statute or administrative designation, or exclusive use for Christmas tree production as indicated by annual shearing.

<sup>4</sup>/Forest land incapable of producing 20 cubic feet per acre of industrial wood under natural conditions, because of adverse site conditions i.e., sterile soils, dry climate, poor drainage, high elevation, steepness, and rockiness.

<sup>5</sup>/Forest land incapable of producing 20 cubic feet per acre of wood under natural conditions and withdrawn for utilization through statute administrative designation.

<sup>6</sup>/Forest land producing crops of industrial wood and not withdrawn from timber utilization by statute or administrative regulation.

<sup>7</sup>/An acre or more of continuous forest land that would otherwise meet the standards for commercial forest land except that it is less than 120 feet wide.

<sup>8</sup>/Areas of land with trees but have less than 16.7 percent stocking and/or are less than 120 feet wide area i.e., cropland with scattered trees, improved pasture with scattered trees, wooded strips, windbreaks, and idle farmland with scattered trees.

**MAJOR FOREST TYPES  
NORTH DAKOTA  
1980**

Figure 1.—Major forest types, North Dakota, 1980.

An important North Dakota resource not included in the forest land area are the 354,300 acres of natural and planted wooded strips and shelterbelts. This area does not include windbreaks around farm buildings and other structures.

The information in this note comes from the second North Dakota forest inventory made during 1978-1980 by the North Central Forest Experiment Station. Other publications giving further details will be available in the future.

## MICHIGAN SAW LOG PRODUCTION AND SAWMILL INDUSTRY, 1978

**James E. Blyth**, *Principal Market Analyst,*  
*North Central Forest Experiment Station,*  
*St. Paul, Minnesota,*

**Jack Zollner**, *Forest Products Utilization Specialist,*  
*Michigan Department of Natural Resources,*

*St. Paul, Minnesota*

**ABSTRACT.**—Michigan's saw log production climbed to 563 million board feet in 1978 from 514 million board feet in 1977. Eight percent was shipped to out-of-State mills. Michigan's 341 active sawmills received 525 million board feet of logs; only 1 percent came from other States.

**KEY WORDS:** Exports, lumber, aspen, oak, maple, pine.

Michigan loggers harvested 563 million board feet of saw logs in 1978, up 10 percent from 1977 (table 1). Eighty-eight percent was hardwood. Nearly three-fifths of the harvest was from three species—aspens, hard maple, and red oak. White pine was the major softwood cut. Major harvest gains were in aspen, maple, and oak; declines were concentrated in pine, spruce, and elm.

Demand was high for pallets, furniture stock, and railroad ties. Markets were good for construction lumber as national housing starts pushed above the 2 million mark in 1978 for the first time since 1973.

Out-of-State sawmills procured 43 million board feet of Michigan logs (table 2, see page 4). Wisconsin was the primary customer, followed by Indiana and Kentucky. The western Upper Peninsula (UP) sup-

<sup>1/</sup>International 1/4-inch rule

plied more than four-fifths of these exports. Pine and aspen comprised three-fourths of the export volume.

Compared to 1977, saw log output rose 68 million board feet in the Lower Peninsula (LP) and fell 19 million board feet in the UP. The northern LP supplied more than two-thirds of the aspen and continued to be the leading saw log producing region. UP producers cut two-thirds of the hard maple; LP loggers cut 97 percent of the red oak.

Producers harvested more than 20 million board feet of saw logs in each of four UP Counties—Houghton, Marquette, Gogebic, and Alger (table 3).

Michigan's 341 active sawmills (21 more than in 1977) received 525 million board feet of saw logs, up 15 percent from 1977. Only 5 million board feet came from other States (table 4). Average annual lumber production per mill continued to climb, reaching 1.54 million board feet. Nineteen mills each sawed more than 5 million board feet and 127 others sawed between 1 and 5 million board feet.

All active sawmills using Michigan logs and bolts were canvassed by means of a formal questionnaire. Canvassing in Michigan was supervised by the Michigan Department of Natural Resources (DNR) with personal contacts at sawmills by DNR personnel and forestry consultants. For a few Michigan mills that did not furnish complete data, DNR wood utilization specialists provided estimates based on prior knowledge

and contacts. The North Central Forest Experiment Station canvassed out-of-State sawmills using Michigan logs and edited and compiled the data.

## SULFUR CONTENT OF UPLAND AND WETLAND VEGETATION IN NORTH CENTRAL MINNESOTA

M. Dean Knighton, *Plant Ecologist,  
Grand Rapids, Minnesota*

**ABSTRACT.**—The sulfur concentration in 138 plant taxa is reported. Significant differences in concentration are noted between some plant life forms and between different environments.

**KEY WORDS:** sulfur cycle, plant life-form, flora, Lake States, acid precipitation.

Industrial and domestic emissions continue to pour into our atmosphere with little understood consequences (Dochinger and Seliga 1976). These emissions contain sulfur and other elements that increase the acidity, or hydrogen ion activity in precipitation. To improve our understanding of how this "acid rain" affects upland and wetland ecosystems in North America, we need to learn more about the sulfur cycle. We also need to identify all related information, and make it readily available. At the Forestry Sciences Laboratory in Grand Rapids, Minnesota, we have been analyzing the sulfur content of vegetation as part of a larger nutrient study. However, because of the urgent need to better understand the sulfur cycle we are publishing this data immediately in its simplest form.

### METHODS

The vegetation was collected from seven water impoundments and one natural deep marsh on the Chippewa National Forest in August of 1976, 1977, and 1978. Samples were collected from 24 1-m<sup>2</sup> systematically located plots in each wetland. The

plots were located on transects that extended from 90 cm-deep water to a point 60 cm above the normal water level. All vegetation was clipped on each plot (including woody species less than 2.5 cm at the base), placed in a plastic bag, and transported to the laboratory where it was either frozen immediately or kept at about 3°C for up to 2 weeks before sorting by species. The vegetation was sorted and oven-dried for 48 hours at 80°C, and then each species was composited. The composited sample was ground in a Wiley mill and thoroughly mixed, then subsampled for analysis. The foliage and wood of woody species were ground together. The analysis was performed at the Research Analytical Laboratory at the University of Minnesota in St. Paul, Minnesota. Digestion was done by nitric and perchloric acids and SO<sub>4</sub> (later converted to S) content determined turbidmetrically with barium chloride (Blanchard *et al.* 1965).

The samples included the natural mineral and biotic material that adheres to submerged plant surfaces. When using and interpreting the data keep in mind this source of sulfur that could not be partitioned.

The species were grouped by life form, and mean sulfur contents were tested for significant differences ( $\alpha=0.05$ ) by analysis of variance and least significant difference methods. Also, values for individual species within life form groups were compared, using simple regression, with values reported for these species by Gerloff *et al.* (1964) in Wisconsin.

## DISCUSSION

Differences in mean sulfur content were significant only between woody and nonwoody plants (table 1). In South Carolina, Boyd (1978) grouped wetland species by life form and reported sulfur contents of 0.31, 0.18, and 0.24 percent for submerged, floating-leaved, and emergent life forms, respectively. These values are remarkably similar to ours (0.31, 0.16, and 0.23 percent), suggesting that real differences may exist in these life forms but that more information is needed to increase statistical sensitivity.

Table 1.—Sulfur content of impoundment vegetation summarized by life form groups

| (In percent)    |  |             |
|-----------------|--|-------------|
| Life form       | Mean sulfur content and 95 percent confidence interval | Species (n) |
| Nonwoody        |  |             |
| Submergents     | 0.31 ± 0.06  | 4           |
| Floating-leaved | 0.16   | 2           |
| Emergents       | 0.23 ± 0.03  | 65          |
| Terrestrial     | 0.21 ± 0.05  | 27          |
| Woody           |  |             |
| Shrubs          | 0.10 ± 0.03  | 25          |
| Trees           | 0.10 ± 0.02  | 15          |

<sup>1</sup>Means are significantly different ( $\alpha$  0.05) between woody and nonwoody groups.

The low sulfur content of shrubs and trees was expected because woody tissue is known for its low sulfur content (Remezov *et al.* 1955). An accurate estimate of sulfur in these species will require partitioning (Young and Carpenter 1967) of the biomass into various components, particularly if they exceed the 2.5 cm basal diameter included in our study.

Our data showed trends similar to those of Gerloff *et al.* in Wisconsin (table 2). Most notable is the indication that emergent species common on submerged to poorly drained soils contain more sulfur than species commonly found on drier sites. Although this observation is supported by Siccama *et al.* (1970) who report a 0.20 percent mean sulfur content for terrestrial vegetation, it must be viewed cautiously in light of Bowen's (1966) report of a 0.34 percent mean for terrestrial vegetation. The values found by Gerloff *et al.* for each life form represented also tend to be higher than the values we found, perhaps because of different analytical methods. When the two data sets were compared species-to-species within groups, no regression coefficient was significantly different from zero ( $\alpha$ 0.05). This result emphasizes the extreme variability of the data and indicates that use of the life form mean for all species within the group is as reliable as individual species values.

Table 2.—Sulfur content of species common to both the present study and to the Wisconsin study by Gerloff *et al.* (1964)

| (In percent)        |  |             |             |
|---------------------|--|-------------|-------------|
| Life form           | Mean sulfur content and 95 percent confidence interval |             | Species (n) |
|                     | Knighton   | Gerloff     |             |
| Nonwoody            |  |             |             |
| Submergents         | -  | -           | 0           |
| floating-leaved     | -  | -           | 0           |
| Emergents           | 0.18 ± 0.10  | 0.26 ± 0.16 | 9           |
| Upland <sup>1</sup> | 0.12 ± 0.06  | 0.21 ± 0.05 | 17          |
| 0.06                |  |             |             |
| Woody               |  |             |             |
| Shrubs              | 0.09 ± 0.02  | 0.11 ± 0.06 | 10          |
| Trees               | 0.08 ± 0.02  | 0.08 ± 0.03 | 6           |

<sup>1</sup>Means are significantly different ( $\alpha$  0.05).

## APPENDIX

Sulphur content of plant species in and around water-impoundments of north central Minnesota. Species names are in accordance with Gleason (1968).

(In percent)

| Species   | Sulfur |      |      | Mean |
|---|--------|------|------|------|
|   | 1976   | 1977 | 1978 |      |
| <b>SUBMERGENTS</b>                              |        |      |      |      |
| <i>Ceratophyllum demersum</i> L.                | 0.34   | -    | 0.40 | 0.37 |

LIBRARY

**ABSTRACT.**—Time study of planting a 3 ha short-rotation intensively cultured plantation on a 1- by 1-m spacing found a productivity of 0.52 ha/hour and planting cost of \$97.87/ha.

**KEY WORDS:** Machine rates, *Populus*, energy plantation, biomass, tree planting

Analyzing the economic feasibility of short-rotation intensively cultured (SRIC) forestry systems requires data on all aspects of establishing, managing, and harvesting such plantations. Because the concept is still being developed and only a few large plantations have been established, accurate data on many of the operations involved have not been available. The USDA Forest Service's Research and Development Program on the Maximum Yield of Wood and Energy from Intensively Cultured Plantations has progressed from small-scale studies of biological principles to larger scale tests of developing technology for establishing SRIC plantations (U.S. Department of Agriculture 1980). Establishment of a 3 ha plantation in May 1980 provided an opportunity to obtain productivity and cost figures for planting a SRIC plantation. Our paper presents the results of a detailed time study of the establishment of that plantation.

The plantation is located on the Harshaw Experimental Farm near Rhinelander, Wisconsin. The farm, a former agricultural site, is now used for research

on SRIC plantations. For this study, an area of sandy loam soil approximately 80 m (262 ft) by 372 m (1,220 ft) was selected for planting. Planting conditions were excellent: the terrain was reasonably level, relatively free of rocks that could interfere with machinery, and fairly dry at the time of planting. The long individual planting runs made this operation a good case study for obtaining accurate planting data that could be characteristic of commercial operations. A commercial operation was approximated by using a uniform 1- by 1-m spacing throughout the planting, and also by using the same planting stock, 20cm (8-inch) long hardwood cuttings of *Populus* clone 9922, primarily 6 to 13mm ( $\frac{1}{4}$  to  $\frac{1}{2}$  inch) in diameter, for the entire operation.

Four planting machines were attached to a common tool bar and towed by a White Field Boss, Model 2-85, 85-horsepower diesel tractor (fig. 1).<sup>1</sup> The units were Mechanical Transplanter, Model CT5, transplanters which utilize chain-driven plant holders to set the planting stock into a continuous furrow. The plant spacing is thus determined by the rotation of the packing wheel that moves the chain holding the

plant holders. A five-person crew is needed in the planting—a tractor operator and four planters, one of whom doubles as the field supervisor. Because of the long planting runs in this operation (372 m), only enough cuttings could be carried on the machines to make a run down the field and back. Therefore, the machines required loading each time they returned to the beginning end of the field.

## RESULTS

Our time study showed that a total time of 5.59 hours was required to plant the 3 ha. Time spent in productive activities was 4.93 hours, or 88.2 percent, while 0.66 hours, or 11.8 percent, was consumed by delays (table 1).

Measurement of the planted area indicated a total plantation size of 2.92 ha (7.21 acres). We estimated that 30,388 cuttings were planted at an average spacing of 0.96 m (3.15 ft) within the rows. The between-row spacing was 1 m (3.28 ft) as determined by the planting machine position on the tool bar. The

measured density was then 10,417 cuttings/ha (4,215 cuttings/acre), very close to the desired density of 10,000 cuttings/ha (4,047/acre). In inspecting the planted area, we saw that the planting was very efficient. We estimated that less than 1 percent of the cuttings were missed, and the cuttings were consistently in the ground to the right depth, covered, and adequately packed with soil.

Based on the time study and measurement of the planted area, the productivity calculated on total elapsed time was 0.52 ha/hour (1.29 acres/hour). Productivity based on actual operating time of the planters was 0.71 ha/hr (1.76 ac/hr). The planting speed was 1.78 km/hour (1.11 miles/hour).

The machine costs for the White 2-85 Field Boss and the Mechanical Transplanter CT5 were calculated as \$13.60 and \$2.55/hour, respectively, or a combined cost of \$16.15/productive hour (table 2) (Miyata 1980). Based on the field study and the machine costs, estimated costs are shown for a typical 8-hour day with 6 productive hours of actual plant-

Table 1.—*Time study results on planting*

| Productive time                          | Hours       | Percent      |

ing (table 3). Production would be 4.26 ha (10.56 acres) for this typical day.

The results of our study can be used to estimate the potential productivity and cost of planting SRIC plantations at various other spacings. If similar equipment is used, the following assumptions form the basis for calculating the productivity of planting at other spacings. From observing the planting in our study, we estimated that the planting machine operators were working at an optimum rate for this type of work; therefore, the rate observed was assumed to be the maximum allowable. We also assumed that the tractor speed could be increased by a factor of three without affecting the working conditions of the operators. So, for a within-row spacing of 3 meters, the tractor speed could be tripled because the rate at which the operators would be functioning would remain the same. The physical limitations on the equipment indicate that a tool-bar length of 4 meters would be maximum without encountering structural problems or turning difficulties. This restriction defines the number of planting machines that can be used on a given between-row spacing as tabulated below.

| Between row spacings (meters) | Planting machines (number) | Strip width planted (meters) |
|-------------------------------|----------------------------|------------------------------|
| 1                             | 4                          | 4                            |
| 2                             | 3                          | 4                            |
| 3                             | 2                          | 3                            |

Table 2.—*Itemized machine rates*  
(In January 1981 dollars)

| Machine                               | Initial cost | Cost/hr (without labor) |           |       |
|---------------------------------------|--------------|-------------------------|-----------|-------|
|                                       |              | Fixed                   | Operating | Total |
| White 2-85 Field Boss                 | 29,260       | 6.53                    | 7.07      | 13.60 |
| Mechanical Transplanter CT5 (4 units) | 2,945        | 2.32                    | .23       | 2.55  |

We also assumed that the planting machines are in operation 75 percent of the total scheduled time, and the other 25 percent of the time is spent in loading, turning, and various delays. Based on these assumptions, the projected productivity for planting SRIC plantations on various spacings are as follows:

| (meters between rows × meters within rows) | Productivity hectares/hr | (acres hr) |
|--|--------------------------|------------|
| 1 × 1                                      | 0.53                     | (1.32)     |
| 1 × 0.5                                    | .27                      | (0.66)     |
| 2 × 2                                      | 1.60                     | (3.95)     |
| 2 × 1                                      | .80                      | (1.98)     |
| 3 × 3                                      | 2.41                     | (5.95)     |
| 3 × 2                                      | 1.60                     | (3.95)     |
| 3 × 1                                      | .80                      | (1.98)     |

The cost of planting SRIC plantations on these spacings, based on the results of our case study, would be as follows (January 1981 dollars):

| Spacing | Cost dollars/ha | (\$/acre) |
|---------|-----------------|-----------|
| 1 × 1   | 97.87           | (39.48)   |
| 1 × 0.5 | 193.00          | (78.95)   |
| 2 × 2   | 28.54           | (11.56)   |
| 2 × 1   | 57.08           | (23.06)   |
| 3 × 3   | 16.27           | (6.59)    |
| 3 × 2   | 24.51           | (9.93)    |
| 3 × 1   | 49.01           | (19.80)   |

Table 3.—*Planting costs*  
(In January 1981 dollars)

|                          | Total         | Cost/ha      | Cost/acre    | Percent      |
|--------------------------|---------------|--------------|--------------|--------------|
| Machine cost             | 96.90         | 22.75        | 9.18         | 23.3         |
| Labor <sup>1</sup>       | 224.00        | 52.58        | 21.21        | 53.7         |
| Supervision <sup>1</sup> | 96.00         | 22.54        | 9.09         | 23.0         |
| <b>TOTALS</b>            | <b>416.90</b> | <b>97.87</b> | <b>39.48</b> | <b>100.0</b> |

<sup>1</sup>Labor rates are assumed to be \$6 hr for planters, \$10 hr for operators, and \$12 hr for supervisors all rates including 30 percent for fringe benefits

## DISCUSSION

The operation studied was obviously very efficient. The planting machines operated almost 75 percent of the time, and the delays, excluding rest breaks, were only about 7 percent of the total time. This indicates both a well-trained, experienced crew and good field conditions.

Labor was the major cost of this operation, comprising more than 50 percent of the planting cost. For any significant reduction in the planting costs, automated planting equipment would be needed to reduce the number of operators required on the planting machines. In addition to reducing cost, automated planting equipment could increase productivity. There is only about a 2-month season for planting SRIC plantations in the Lake States. Based on our case study, one planting crew could plant only about 180 ha (445 acres) on a 1- by 1-m spacing in

this time. If a wider tree spacing, such as 2 by 2 m, proves economically feasible, the planting acreage would increase. However, for planting large acreages per year, such as may be required commercially, planting technology must be improved.

## SEASONAL VARIATIONS IN ASH CONTENT OF SOME MICHIGAN FOREST FLOOR FUELS

NOV 3 1987

Robert M. Loomis, *Fire Management Scientist,  
East Lansing, Michigan*

CLEMSON  
LIBRARY

**ABSTRACT.**—Samples from the forest floor litter layer were collected seasonally from under medium to fully stocked large sapling to sawtimber stands in Lower Michigan to study seasonal ash content changes. The total ash and silica-free ash content of tree foliage in the upper part of the litter layer differed little from season to season. Differences in ash content due to species were generally more important than those due to season. The total ash content of an entire northern hardwood-oak-hickory forest litter layer increased significantly (0.01 level) through the year; however, silica-free ash content did not. Bracken fern did not change significantly in either total ash or silica-free ash content.

**KEY WORDS:** Fuel modeling, fuel characteristics.

The National Fire-Danger Rating System (Deeming *et al.* 1977) and Albin (1976) fire behavior models are used by fire managers to predict fire behavior. These systems utilize the Rothermel (1972) fire behavior model, which includes total ash and the silica-free ash content of fuel as variables. The ash (or noncombustible) constituents of organic material are of concern to the fire manager because they usually reduce the combustion rate. Not all of them are equally effective, however. And one of them, silica, is completely inert in the combustion process—hence the special interest in silica-free ash.

Forest floor litter (L-layer)<sup>1</sup> is a primary fuel of wildland fires in many ecosystems, so its silica-free

and total ash content are needed in using the above systems to predict fire behavior. Further, it is important for the fire manager to know whether ash content of litter varies from season to season. Therefore, we conducted a study of the seasonal influence on ash content for certain forest floor fuels in Lower Michigan.

### METHODS

The study was done in Ingham, Roscommon, and Wexford Counties. From the forest floor litter layer we collected leaves of 10 tree species: white oak (*Quercus alba* L.), northern red oak (*Quercus rubra* L.), northern pin oak (*Quercus ellipsoidalis* Hill), American beech (*Fagus grandifolia* Ehrh.), large-toothed aspen (*Populus grandidentata* Michx.), sugar maple (*Acer saccharum* Marsh.), shagbark hickory (*Carya ovata* (Mill.) K. Koch), red pine (*Pinus resinosa* Ait.), white pine (*Pinus strobus* L.), and jack pine (*Pinus banksiana* Lamb.). In addition, bracken fern (*Pteridium aquilina*) and the entire litter layer under a mixed northern hardwood-oak-hickory stand were sampled.

<sup>1</sup>The litter, or L-layer, is the uppermost layer of the forest floor and consists of loose, dead needles, leaves, grass, twigs, etc.

Samples were collected five times between June 1973 and July 1974: in the early summer (June-July), late summer (August-September), fall (October-November), spring (April), and again in early summer (June-July). (Late summer samples were not collected for all species.) Most of the materials collected were less than 1 year old and were at the top of the litter layer.

Each sample consisted of about 10 grams of material; 3 to 10 samples were collected per species at each location. Samples were obtained under medium to fully stocked large sapling to sawtimber stands.

Samples were oven dried for 72 hours at 70°C and then ground in a Wiley Mill to pass a 20-mesh screen. Ash content was determined according to standard methods (American Society for Testing and Materials 1971, Association of Official Analytical Chemists 1965).

Total ash and silica-free ash content were determined by season for (1) tree foliage, by species, found

at the top of the litter layer; (2) the entire litter layer of a mixed northern hardwood-oak-hickory stand; and (3) cured bracken fern (table 1).

The t-test was used to examine ash content differences related to species, location, and season.

## RESULTS AND DISCUSSION

Silica-free ash content reduces combustion rate and is independent of heat content (Philpot 1968). Total ash increases with time (Kucera 1959) and also reduces combustion rate. As the litter layer merges with the lower forest floor, the ash content generally increases (Hough 1969, Hough and Albini 1978, Roussopoulos<sup>2</sup>).

<sup>1</sup>Silica-free ash content values in parentheses.

Mineral content generally increases with time because breakdown of the organic portion usually proceeds faster than leaching of minerals. Plant material decomposition is controlled by the chemical make-up of the material and by environmental factors. Therefore, many variables and interactions are involved in the process.

Species appear to have more effect than season or location on ash content and thus on fire behavior. Tests for seasonal differences in ash content for each species by location were inconclusive,<sup>3</sup> but total ash content increased with time since foliage fell more than did silica-free ash. Examination of effects of season, by species of foliage, on predicted fire reaction intensity (Btu/ft<sup>2</sup>/min) and rate-of-spread (ft/min) indicated seasonal intensity differences that ranged from 0 to 4 percent for total ash and from 0 to 5 percent for silica-free ash content. Predicted intensity differences due to species differences within seasons ranged from 6 to 10 percent for total ash and from 5 to 12 percent for silica-free ash content.

Total ash content of the combined northern hardwood-oak-hickory litter layer significantly increased from fall to late summer, but the silica-free ash content did not. Bracken fern showed no significant changes in either total or silica-free ash content from fall through early summer.

Total ash content and silica-free ash content, in general, differed between species and increased with passage of time following leaf fall, although not always significantly. Species of foliage litter material is usually more important for predicting fire behavior than seasonal differences in ash content.

**ABSTRACT.**—Discusses problems associated with fire-cause data on USDA Forest Service wildfire reports, traces the historical development of wildfire-cause categories, and presents the pros and cons of retaining current wildfire-cause reporting systems or adopting new systems.

**KEY WORDS:** Wildfire causes, wildfire reports, wildfire prevention.

Wildfire causes, entered on USDA Forest Service fire reports since 1905, are key elements in the development and analysis of Forest Service fire prevention programs. First devised to pinpoint how fires started, fire-cause categories were later expanded to include the persons responsible. The basic objective of these classifications is still to identify major fire causes, thereby helping land managers select fire prevention programs and allocate prevention resources<sup>1</sup>

Due to several problems, however, accurate fire-cause information is often difficult to collect and report. This paper focuses on problems associated with documenting field data on the Forest Service Individual Fire Report, Form 5100-29. Persons making fire-cause entries on this form face two primary obstacles. The first is selecting the best fire-cause and

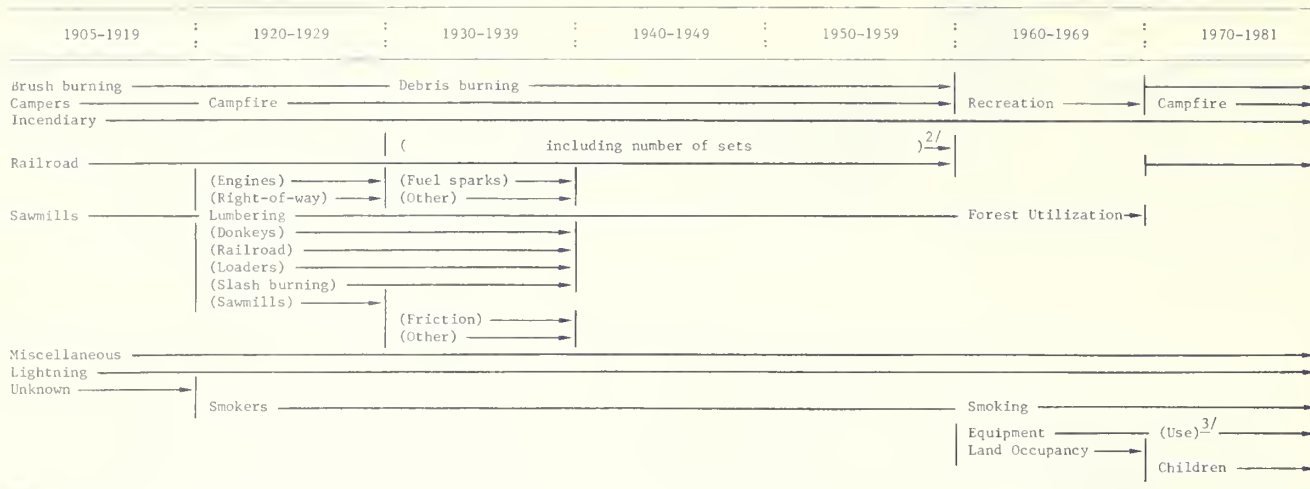

<sup>1</sup>The focus is on human-caused wildfires because lightning fires are basically not preventable.

class-of-people classification scheme from a few overlapping categories which are frequently broad and repetitious. The second is reporting the reliability of fire-cause information. The roots of the first problem lie in the historical development and use of fire-cause categories in the Forest Service; the second is a matter of form design.

The current (1970) Forest Service fire report contains four cause-related items (statistical cause, general cause, specific cause, and class-of-people) which evolved from the reporting system implemented in 1905.<sup>2</sup> The first fire-cause classification system used by the Forest Service contained eight general categories: brush burning, campers, incendiary, railroad, sawmills, miscellaneous, lightning, and unknown. These were expanded in the 1920's and 1930's, reflecting a need for greater fire-cause detail (table 1a). Except for a few minor changes, these general-cause categories remained fairly consistent for 40 years. In 1960, general fire-cause classifications were expanded and divided into two lists, statistical and land-use (table 1a, 1b). In 1970, land-use causes were renamed general causes, but both lists were retained

<sup>2</sup>Statistical causes are used primarily for compiling periodic, general information reports. General causes show the major types of land-use activities responsible for fires, and specific causes show detailed activities or ignition sources of fires. Class-of-people refers to the group of persons to which an individual responsible for a fire ignition belongs.

Table 1a.--General/statistical cause categories: 1905-1981<sup>1/</sup>

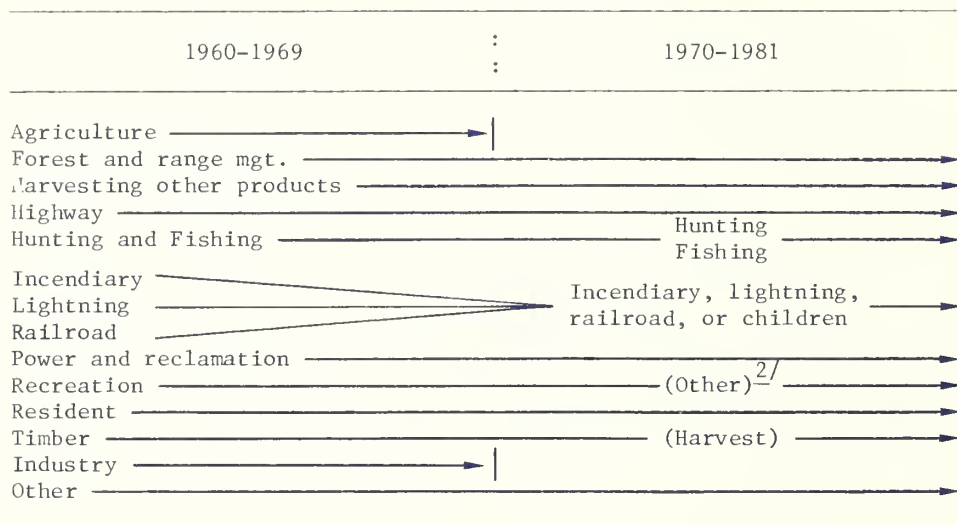

<sup>1/</sup> In 1960 general causes were renamed statistical causes.

<sup>2/</sup> Parentheses under the line show additional information reported with the primary general cause.

<sup>3/</sup> Parentheses on the line show words added later to supplement or clarify the cause classification.

Table 1b.--Land use/general cause categories used in conjunction with statistical cause<sup>1/</sup>

<sup>1/</sup> Land use categories from the 1960 decade were renamed general causes in 1970.

<sup>2/</sup> Parentheses on the line show words added later to supplement or clarify the cause classification.

in a slightly modified form. Even with all these changes since 1920, six of the eight general-cause categories, although slightly modified, are still used today: debris burning, campfire, incendiary, railroads, miscellaneous, and lightning. Approximately three-fourths of the specific-cause categories have been retained, although modified since their introduction in 1940 (table 2).

Instituted in 1920, class-of-people categories remained fairly uniform for 40 years before their extensive revision in 1960 (table 3).

Looking over the past 75 years of changes in fire-cause reporting, however, we can conclude that fire-cause categories have changed little in form. While this lack of change ensured consistency of fire report

data, it also created a major problem cited above—overlapping and repetitious fire-cause categories.

Statistical and general fire causes, for instance, include a combination of overlapping categories; as a result, more than one cause class can be assigned to a given fire. These causes include categories of people (children, resident), activities involving intentional use of fire (e.g., camping, debris burning, smoking, incendiarism), and work-related or recreation activities incidentally causing wildfires (e.g., equipment use, timber harvest, fishing, hunting) (table 1a, 1b). In addition, individuals responsible for causing wildfires can be classified in many ways using the current class-of-people categories (table 3). For example, a person could be both an owner and a local permanent or both a permittee and seasonal resident. Such overlapping categories result in multiple classification schemes for a given fire cause and make it difficult to determine from fire-report statistics the actual cause and person responsible for a

particular wildfire. To illustrate, a dump fire set by one or more unidentified persons is reported in Region 9 using seven different cause and class-of-people combinations (table 4).

Compounding the problem of overlapping categories is the broad (one category encompasses a host of situations) and repetitious nature of the fire-cause reporting system. A classic example of this problem is the use of the following categories to describe a known fire cause:

| Statistical   | General | Specific | Class-of-People |
|---------------|---------|----------|-----------------|
| Miscellaneous | Other   | Other    | Other           |

An investigation revealed that a wildfire was started by an unidentified person who, after lighting a cigarette and falling asleep in bed, ignited the mattress. Upon awakening and finding the mattress on fire, he dragged it out of a bunkhouse and abandoned

Table 4.--Classifications of dump fires in Region 9

| Statistical cause | General cause | Specific cause | Class-of-people |
|-------------------|---------------|----------------|-----------------|
| 1. Incendiary     | Incendiary    | Burning dump   | Local permanent |
| 2. Incendiary     | Incendiary    | Grudge         | Local permanent |
| 3. Debris burn    | Other         | Trash burning  | Visitor         |
| 4. Debris burn    | Resident      | Burning dump   | Local permanent |
| 5. Debris burn    | Incendiary    | Trash burning  | Local permanent |
| 6. Debris burn    | Other         | Burning dump   | Local permanent |
| 7. Miscellaneous  | Resident      | Burning dump   | Local permanent |

it in the woods, starting a wild fire. For lack of a better method, this fire was reported as "Miscellaneous, Other, Other, Other." Although this example may be atypical, it does illustrate the information lost when a reporter classifies a fire-cause using the current system. Even though many fire causes can be pinpointed accurately and facts essential to a sound fire prevention campaign can be assembled, this information is either frequently submerged in a few broad, repetitious fire-cause categories, or it is not recorded at all.

A second major reporting problem is the lack of adequate methods for indicating the reliability of fire-cause data (Main and Haines 1974). Some causes are known with such certainty that legal action can be taken, but others are completely unknown. Once entered on a fire report form, however, reliable causes are indistinguishable from unreliable ones. With no "unknown" category available, an unknown cause is classified typically as a smoking, an incendiary, or a miscellaneous wildfire. Because reporters cannot indicate the reliability of fire causes but must report both known and unknown causes, the accuracy of fire-cause data is often highly questionable, leading to erroneous assumptions about fire prevention problems.

## DISCUSSION AND CONCLUSIONS

Decade-to-decade modifications in the Forest Service fire-cause reporting system during the past 75 years brought little more than cosmetic change. As a result, we have inherited a system that has flaws but is relatively simple to use and historically compatible with previous fire report data.

One of the dilemmas facing managers today is whether to maintain the current system, modify it, or replace it.<sup>3</sup> Resolving this dilemma depends, in part, on how the data are used and to whom they are most important. If, for example, upper level managers need general fire-cause information for annual reports and statistics, budgetary and financial assistance requests, or other administrative purposes, the current system is probably adequate with little or no modification. On the other hand, the current system does not provide the data needed to plan, implement, and analyze fire prevention programs in

---

<sup>3</sup>*Because many State and Federal agency fire-cause reporting systems are similar in many respects to the Forest Service system, this problem also faces fire managers outside the Forest Service.*

as much detail and as accurately as fire prevention specialists might desire. Two possible remedies would be to modify the current system or adopt a completely new one. Although the first alternative again involves cosmetic change, it does ensure historical data compatibility. With a few improvements (e.g., including "certainty of cause" categories; expanding categories; analyzing and standardizing reporting procedures for a given fire cause such as dump fires), it also eliminates some of the problems cited above, thereby increasing data accuracy and reliability. The second alternative, going to a new and perhaps better reporting system, may also be beneficial. One method, called the "Building Block" system, is currently under consideration by State and Federal land managers.

This system includes multiple categories that classify the form of heat energy (e.g., flames, sparks, and hot surfaces from a variety of sources) that ignited the fire; the equipment that provided the heat that started the fire; the type of material or kindling fuel first ignited; and the reason why the form of heat energy and the material first ignited combined to start a wildfire. It also incorporates into the class-of-people categories the types of persons responsible for fires and the person's age, sex, and primary activity when the fire started. Even though the Building Block system has some drawbacks, such as its lengthiness, it does eliminate the problems with the current system and yet enables statistical fire-cause categories, as we presently know them, to be identified.

No fire-cause reporting system will ever be perfect. But, fire managers, when deciding which system to use, must consider the information they need and the level of resolution, the degree of error they are willing to accept, and the operational simplicity or difficulty of each system. These factors must also be weighed with the current drive to adopt a standardized State and Federal fire-cause reporting system and with the desire to maintain historical data compatibility.

**ABSTRACT.**—Describes calculator programs that simulate the growth and thinning of a stand. Also includes a method of computing maximum yield, allowing a comparison of potential and actual yields of a stand.

**KEY WORDS:** Dynamic programming, growth and yield, maximum biomass production.

One decision a forest manager must make is whether to thin a stand of trees now or to wait until the trees have grown more. A decision to thin implies another decision: how much to thin.

To make these decisions easier, the growth and thinning of a stand can be simulated on a programmable calculator by using an equation that predicts basal area growth per acre in a stand. For programs in this paper, we used the equation  $\Delta B = aB - bB^m$ , where  $\Delta B$  is periodic basal area growth per acre,  $B$  is basal area per acre, and  $a$ ,  $b$ , and  $m$  are numerical constants specific to tree species, location, stand age, and length of growth period. Aided by a calculator, the forest manager can easily compare several thinning schedules before acting.

Figure 1 represents the growth and thinning process over a rotation. The total yield produced is the sum of all the cuts; the final harvest is the clearcut.

2. Average height of dominant and codominant trees in the stand
3. Current basal area per acre (ft<sup>2</sup>/ac)
4. Site index
5. Age at final harvest
6. Coefficients for basal area growth equation.

Respective sources of information are:

1. Landowner's records or increment boring
2. Field measurements with a hypsometer
3. Field sample with angle gauge or tree measurement
4. Figure 2 (use height and age to read site index)
5. Rotation age chosen by owner (based on management objectives)

Figure 1.—Schematic stand development with 4 thinnings prior to a final clearcut.

## FIELD DATA COLLECTION

Information needed to run the program:

1. Age of stand

Figure 2.—Red pine site index curves (Lundgren and Dolid 1970).

- Research that fits the growth equation to observations of stand growth. The growth equation coefficients used in the examples in this paper apply to 10-year periodic basal area growth per acre for red pine plantations in the Lake States.

## CALCULATION PROCEDURE

Programs that compute thinning schedules have been designed for the Texas Instruments 59 calculator (with and without a printer) and the Hewlett Packard 67 and 97 calculators<sup>1</sup>. Briefly, the programs operate as follows: After obtaining needed information, the user loads the program into the calculator, enters information into data registers, chooses a thinning schedule, and then presses a series of keys to run the program. Calculations are performed in the following sequence at the beginning of each 10-year period:

- The desired residual basal area is determined (based on the chosen thinning schedule) and compared to the actual standing basal area.
- If the desired residual basal area is smaller than the actual standing basal area, the amount to cut is calculated and subtracted from the actual standing basal area.

<sup>1</sup>Mention of trade names does not constitute endorsement by the U.S.D.A. Forest Service.

- Growth for the next 10-year period is determined and added to the residual basal area.
- This process is repeated through the rotation to the final harvest.

At the beginning of each period, this calculator provides the following stand information: age, initial basal area (BAI), average height of dominant trees (HT), optimal residual basal area for maximum basal area growth (OPTB), optimal residual basal area for maximum cubic foot volume growth (OPTV), amount to cut in square feet per acre (CUT), cumulative basal area cut plus current residual basal area (CUT/ABA), basal area growth for the next 10 years (GROW), cumulative volume (VOL), and mean annual volume increment (MAI).

## COMPARING MANAGEMENT OBJECTIVES

Programs have been designed to compute six thinning schedules that depend on different management objectives: (1) maximize cubic foot volume production, (2) maximize basal area production, (3) make no intermediate cuts, (4) follow the schedule to maximize cubic foot volume production but allow only a minimum feasible cut, (5) cut the same amount at each period, and (6) cut to a chosen residual basal area.

The residual basal area is computed for the first two schedules at the beginning of each 10-year period. These options appear in the tables under the headings OPTV and OPTB, respectively. By producing values that lead to maximum results, these two schedules provide a standard against which other schedules can be compared. The user can run them in addition to the other schedules to compare the potential and the actual yield of a stand. The other four schedules will yield less than the maximum but may be followed due to economic or other considerations.

The age at which mean annual increment reaches a maximum can be determined by finding the highest value in the MAI column (tables 1 and 2) and reading across to the age. This age could be used as the rotation age if compatible with the management plans.

Table 1 illustrates the optimum thinning schedule for maximum volume production and table 2 shows the effects of no intermediate thinning on the same stand. The difference in cubic foot volume production is 1335.3 ft<sup>3</sup>. The graph shows the growth pattern and the difference in total volume production.

## SAMPLE THINNING SCHEDULES

The sample thinning schedules, illustrated in tables 1 and 2, and figure 3, are geared to a stand having the following characteristics: Age = 20 years

Basal area = 165 ft<sup>2</sup>/acre

Site index = 66

Final harvest at 80 years

A more detailed discussion is presented in:

Chen, C. M.; Rose, D. W.; Leary, R. A. How to formulate and solve optimal stand density over time problems for even-aged stands using dynamic programming. Gen. Tech. Rep. NC-56. St. Paul, MN: U.S. Department of Agriculture, Forest Service, North Central Forest Experiment Station; 1980. 22 p.

## TIMBER VOLUME IN EASTERN SOUTH DAKOTA, 1980

PUBLIC DOCUMENT  
 DEPOSITORY ITEM

FEB 27 1983

Ronald L. Hackett  
 Associate Mensurationist

CLEMSON  
 LIBRARY

**ABSTRACT.**—Eastern South Dakota's 113,600 acres of commercial forest land supported 51.9 million cubic feet of growing stock in 1981. This is a decrease in timber volume of 24 percent since the last inventory in 1965. The decrease was entirely in hardwood species. Cottonwood is the most abundant tree species—it accounts for 33 percent of the growing-stock volume and comprises 44 percent of the sawtimber volume. Shannon County in the southwestern part of the State contains the largest amount of timber volume.

**KEY WORDS:** Growing stock, sawtimber, species, counties.

Eastern<sup>1</sup> South Dakota's 113,600 acres of commercial forest land supported 51.9 million cubic feet of growing stock<sup>2</sup> in 1980. This is a decrease of 24 percent since the last inventory in 1965. As shown in the following tabulation the decrease was entirely in hardwood species—softwood volume remained the same:

| Species group | Growing-stock volume |      |
|---------------|----------------------|------|
|               | <sup>1</sup> 1965    | 1980 |
| Softwoods     | 11.9                 | 11.9 |
| Hardwoods     | 56.3                 | 40.0 |
| Total         | 68.2                 | 51.9 |

(Million cubic feet)

The average growing-stock volume per acre increased slightly from 412 cubic feet (3.2 cords per acre) in 1965 to 457 cubic feet (3.6 cords per acre) in 1981. This is due, in part, to increased volume by stand age of commercial forest land base.

Cottonwood is the most abundant tree species in eastern South Dakota and accounts for 33 percent of the growing stock volume (table 1). Its volume, however, has decreased by 3.9 million cubic feet (18 percent) between inventories. Ash, the second most plentiful species in the State, showed a decrease of 3.1 million cubic feet from 1965 to 1980. The third most plentiful species is ponderosa pine, which decreased only 0.6 million cubic feet in the 15 years between inventories. These three species make up about four-fifths of the growing-stock volume in eastern South Dakota. The following tabulation compares growing-stock volumes by species for both surveys.

<sup>1</sup>East of the 103rd Meridian (near Rapid City) in South Dakota. The area west of the 103rd Meridian (Harding, Butte, Lawrence, Fall River, Meade, Pennington and Custer Counties) is inventoried by the Intermountain Forest and Range Experiment Station, Ogden, Utah.

<sup>2</sup>Net volume of all live merchantable trees 5 inches d.b.h. and larger from the stump to a variable 4-inch top diameter outside bark of the central stem. Does not include limbs or cull tree volume.

<sup>3</sup>Figures from the 1967 survey have been adjusted because of changes in survey procedures and definitions.

Table 1.--Net volume of growing stock on commercial forest land by species group and county, South Dakota, 1980.  
(In thousand cubic feet)

| County      | Softwoods   |                |                         |                 |       |          |            |       |       |            | Hardwoods |           |                 |         |           |           |           | Total hardwoods |

Included in the growing-stock volume are 176 million board feet in sawtimber trees.<sup>c</sup> The average sawtimber volume per acre is 1,552.8 board feet. As with growing stock, cottonwood is by far the leading sawtimber species in eastern South Dakota and comprises 44 percent of the volume. Ponderosa pine is ranked second and accounts for 22 percent of the total sawtimber volume. Ash, oak, and elm account for most of the remaining sawtimber volume as shown in the following tabulation:

| Species        | Sawtimber<br>(Thousand board feet) <sup>c</sup> |
|----------------|---|
| Cottonwood     | 77,328  |
| Ponderosa pine | 38,644  |
| Ash            | 31,936  |
| Oak            | 9,832   |
| Elm            | 7,833   |
| Other species  | 10,827  |
| Total          | 176,400   |

<sup>a</sup>Other softwoods are Rocky Mountain juniper and eastern red cedar.

<sup>b</sup>Other hardwoods are honey locust, red mulberry, eastern hophornbeam, chokecherry, Canada plum, wild plum, and aspen.

<sup>c</sup>Net volume of live merchantable sawtimber trees (softwoods 9.0 inches d.b.h. or larger and hardwoods 11.0 inches d.b.h. and larger) from the stump to a point in the central stem at which utilization for sawn products is limited by large branches, forks, or other defects, or by a top diameter outside bark of 7.0 inches for softwoods and 9.0 inches for hardwoods.

International 1/4-inch rule.

Timber is concentrated primarily in the major river basins of Southwestern, Western, and Southern regions of eastern South Dakota. Shannon County in the southwestern part of the State contains the largest amount of timber volume (22 percent of the total), with 11.5 million cubic feet of growing stock and 38.5 million board feet of sawtimber volume (table 2). Sixty-nine percent of the total ponderosa pine growing-stock volume and 8 percent of the total cottonwood volume is found in Shannon County.

These statistics are based on results from the forest inventory conducted by the North Central Forest Experiment Station. Fieldwork for the inventory was completed in July 1980. This is one of a number of reports that will be prepared presenting resource statistics for Eastern South Dakota.

Sampling error for eastern South Dakota's total growing-stock volume of 51.9 million cubic feet is estimated to be  $\pm 40$  percent. Sawtimber sampling error is estimated to be  $\pm 30$  percent for the total of 176.4 million board feet.

Table 2.--Net volume of sawtimber on commercial forest land by species group and county, South Dakota, 1980.

# A TECHNIQUE FOR TRAPPING FUNGAL SPORES

Michael E. Ostry, *Associate Plant Pathologist,*  
and Thomas H. Nicholls, *Principal Plant Pathologist*

**ABSTRACT.**—Describes a technique for using petroleum jelly-coated microscope slides to determine the spore dispersal patterns of fungi that cause diseases of nursery, plantation and forest trees.

**KEY WORDS.**—Disease, pest management, infection, trees, phenology, spore traps.

Early detection, identification, and study of a forest pathogen is essential to prevent a potential epidemic and subsequent economic loss. The biology and life history of a disease-causing organism should be understood, if its controls are to be effective. Spore traps have been used to study the life cycles of fungi and also can be used as a forecasting tool to monitor the presence of certain tree pathogens. The information gained from these traps is extremely useful for planning the control of many forest pathogens. We have successfully used Vaseline<sup>1</sup> petroleum jelly-coated microscope slide spore traps to determine the timing of spore release and dissemination for several serious fungal pathogens in the Lake States. Timing of spore release is particularly important for applying chemical sprays. Knowledge of proper spray timing eliminates extra sprays, which are costly and introduce needless pesticides into the environment.

## SPORE TRAP OPERATION

Spore traps are placed in and around infected trees at various heights and distances. These traps are

<sup>1</sup>Mention of trade names does not endorse the products by the USDA Forest Service.

then changed at weekly intervals throughout the season. All slides should be changed on the same day for easy comparison. Potted seedlings, used as exposure trees, can also be placed under infected trees and changed at weekly intervals to determine exact timing of infection. After exposure, the trees are moved to an area free of the disease and observed for the occurrence of disease symptoms. Data from the spore traps and exposure trees can be used to determine when spores are released and when host trees are infected. By graphing spore dispersal data it can be determined when peak amounts of spore inoculum are present (fig. 1-3). Control measures can then be applied prior to and during these peaks to ensure complete protection. Most chemical controls are preventative so must be applied before spores are released to be effective.

The following methods are used to prepare vaseline spore traps for the field and to examine them in the laboratory.

## METHODS FOR MAKING VASELINE SPORE TRAP SLIDES

1. Obtain slides that have one frosted end.
2. Fill 2 or more 300 ml beakers two-thirds full of water and place an amount of vaseline in the water so that when it melts there will be approximately a 1-inch layer floating on top. SLOWLY heat the beakers on separate hot plates until vaseline melts to a clear, yellow color. This is usu-

Figure 1.—*Sirococcus strobilinus* spore dispersal from red pine correlated with rainfall, Superior National Forest, Minnesota, 1973.

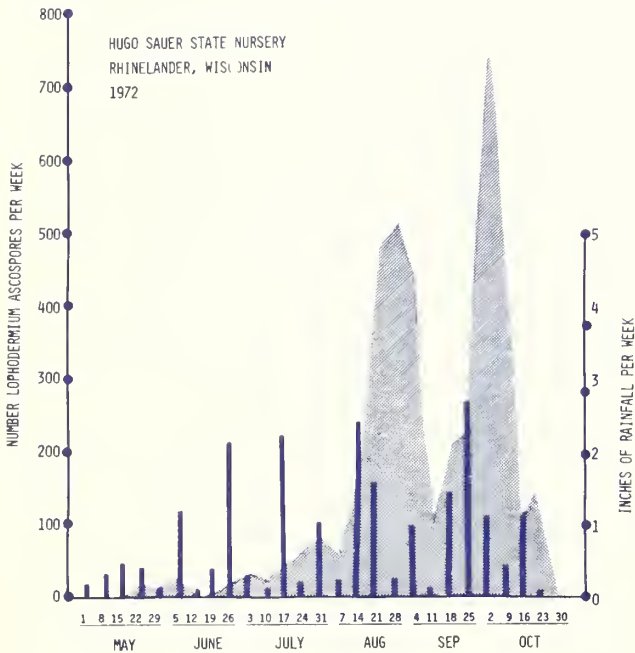

Figure 2.—*Lophodermium needlecast* spore dispersal from red pine nursery seedlings correlated with rainfall, Hugo Sauer State Nursery, Rhinelander, Wisconsin, 1972. Note that the major spore dispersal peak for *Sirococcus* shoot blight (fig. 1) is in the early part of the growing season and that for *Lophodermium* occurs in the latter part of the growing season. Therefore, timing of control measures are different for the two diseases.

LOPHODERMIIUM SPORE RELEASE DATA FOR MINNESOTA, WISCONSIN, MICHIGAN, INDIANA 1969 - 1972

Figure 3.—*Lophodermium* spore release data for Minnesota, Wisconsin, Michigan, and Indiana showing how data can be combined to produce a regional spore dispersal graph that can help forest manager's initiate controls at the proper times.

ally between 65 and 80° C. DO NOT BOIL. Temperature is critical—if it is too cool, vaseline will not adhere smoothly to slides; if it is too hot, vaseline will melt off the sides of slides as they are being dipped. Use several beakers because the water temperature will drop as slides are dipped. Also, more vaseline must be added and melted when the level in the beaker is less than inch thick.

3. Dip two slides at a time. Apply a drop of water to the back of one slide and place it back to back (FROSTED SIDES OUT) with another. Holding onto the frosted end, dip the slides into the beaker of melted vaseline using a SMOOTH, vertical motion up to about 1/8-inch from the frosted end. Do not let frosted ends become covered with vaseline. Separate slides and place on a paper towel to cool. Use a spatula to scrape excess vaseline off edges of slides and remove approximately 1/8-inch of vaseline from the end so that it will not smear when the slide is placed in a slide box. The finished slide should have a smooth surface. If it does not, refer to the following trouble shooting guide to determine the cause of the problem.

# TROUBLE SHOOTING GUIDE

| Problem   | Cause  | Solution   |
|---|--|--|
| Vaseline surface lumpy, irregular                               | Water/Vaseline too cool, jerky motion in dipping slides  | Reheat water; dip slides using a smooth, nonstop motion      |
| Vaseline surface too thin or melted off near the edges of slide | Water/Vaseline too hot, dipping too slow so that water heats the slide & melts Vaseline as slide is dipped | Let water/Vaseline cool, dip slides faster                   |
| Bubbles on Vaseline surface of slide                            | Water/Vaseline boiling   | Use lower heat setting, let water/Vaseline cool before using |

**CAUTION:** Do not leave heating beakers unattended; do not boil; use care in handling hot, slippery beakers; do not allow Vaseline to spill onto heating coils. When reheating a beaker of water with Vaseline that has solidified, break up the surface to prevent a boil-over.

#### 4. Label the Slides

The following is an example of a method that can be used to code exposure slides. Use a hard (4H) lead pencil to avoid smearing.

| Frosted End                      | —Vaseline— |
|----------------------------------|------------|
| * SS 1<br>4-3-78<br>4-10-78<br>A |            |

Exposed from 4-3-78 to 4-10-78  
Spore Trap Location A

5. Keep coated slides in a cool place. They can be stored at room temperature or, preferably, in a refrigerator.

Exposed slides placed in slide boxes can be sent from field locations to laboratories using carefully padded mailing boxes to avoid breakage.

#### 6. Make Spore trap holders.

They can be made from aluminum clothesline or similar wire. Bend one length of wire to shape and hold the frosted end of the slide in place by two bends in the wire and by a spring clothespin (fig. 4). For best results in the field, keep slides horizontal and keep vegetation away from the slides. Place slides in and around the areas being

Figure 4.—Spore trap holder.

monitored. Slides should be positioned under infected trees to ensure trapping spores, especially rain-splash disseminated spores when they are produced. To determine the source or spread of inoculum place slides at known distances in the cardinal directions from infected trees.

#### 7. Read the slide with a microscope.

A cover slip is not necessary if a stain is not used except at high magnifications where it is helpful in preventing vaseline from accidentally smearing the objective. The use of a stain is necessary when counting hyaline or other light-colored spores. Staining can usually be done by placing one drop of lactophenol and one drop of stain in the middle of each transect to be counted. Then gently place

a 24x50mm cover slip on the vaseline and allow the stain to disperse. Avoid using extensive amounts of stain or lactophenol.

The size of spore being counted will determine the magnification needed but it should be the same throughout the study for comparison purposes. For example, we generally use 430X for counting *Diplodia*, *Sirococcus*, and *Gremmeniella* spores.

Make three transects at predetermined locations across the width of each slide as shown below. Then count and total all spores in each transect.

## MONITORING WEATHER AND PHENOLOGY

The development and severity of disease is greatly affected by weather conditions. To study this, we maintain weather stations at each study site where spore traps are located. Each station consists of a weather shelter containing a temperature-relative humidity 7-day recording hygrothermograph and a rain gauge. The phenological development of parasite and host are monitored at weekly intervals using a standard field form. Shoot and foliage elongation and presence of fruiting bodies or needlespots are recorded and correlated with weather and spore release data.

## CONCLUSION

The techniques described in this paper can be used to inexpensively provide knowledge on the biology of a fungus pathogen that is needed to help make accurate control judgments. Control recommendations for one part of the country may not necessarily work for the same species in other areas because of climatic or physiological and genetic differences in hosts and pathogens. Therefore, it may be necessary to adjust timing of control practices for different areas. These adjustments can be made easily and quickly by obtaining the necessary information using these techniques.

D. P. Fowler, *Project Leader, Tree Improvement,*  
*Fredericton, New Brunswick, Canada*

**ABSTRACT.**—*Picea glauca* and *P. smithiana* were successfully crossed. Crossability ranged from 2 to 30 percent depending on the female *P. glauca* parent tree. Early characteristics and growth in Wisconsin and in New Brunswick are described. *P. smithiana* relatedness in the genus is discussed.

**KEY WORDS:** Crossability, seedling characteristics, hybridity, phylogeny.

Species hybridization creates new genotypes that may be superior to the parental species; it can also be used to help determine intrageneric relations among species (Wright 1955).

Himalayan spruce, *Picea smithiana* (Wall.) Boise., is a high elevation (2,000-4,000 m), commercially important species. It extends from eastern Afghanistan southeastward to central Nepal, a distance of approximately 2,000 km. Himalayan spruce is one of the largest spruce species with heights of up to 50 m (Schmidt-Vogt 1977). The species has been planted on a small scale as an ornamental in Great Britain (Streets 1962) and in eastern North America (Wright 1956).

White spruce, *Picea glauca* (Moench) Voss, is the most widely distributed conifer in North America. The species has been extensively planted throughout the north-central and northeastern United States and adjacent Canada during the last 40 years. White spruce is known to be highly variable with a great potential for genetic improvement (Nienstaedt and Teich 1971).

Mergen *et al.* (1965) were the first to attempt to cross white spruce and Himalayan spruce. They obtained 852 seeds from 32 cones but provided no information on proportions of full seed or on germinations. At least 40 seeds germinated and survived for 4 years in a nursery. At the end of the first growing season, the hybrids were not significantly different from white spruce. At the end of the fourth growing season in the nursery, their heights were intermediate between white spruce seedlings obtained from self- and from wind-pollinations.

Fowler *et al.* (1973) reported obtaining 144 full seeds from 443 cones from crosses of three white spruce with pollen of Himalayan spruce. Later Fowler *et al.* (1975) obtained 14 full seeds from 310 cones from this same cross on nine additional white spruce at the Acadia Forest Experiment Station (AFES) near Fredericton, New Brunswick. The same cross using 42 female strobili on three trees was reported as successful by Hoffman and Kleinschmit (1979).

We present additional information on some crosses reported by Fowler *et al.* (1975) and on crosses made at the Forestry Sciences Laboratory (FSL) in Rhineland, Wisconsin.

## MATERIALS AND METHODS

In the spring of 1971, an attempt was made to cross three white spruce trees growing at the AFES

with pollen from a single Himalayan spruce growing in the Yale Brett Arboretum in Fairfield, Connecticut. This same combination, as well as intraspecific white spruce crosses, was attempted again in 1973 using nine other white spruces at the AFES, one at Taymouth, N.B., and four white spruces at the FSL.

The pollination techniques used were essentially the same as those described for white spruce by Nienstaedt and Teich (1971). The general procedures used for seed cleaning and germination and for raising and testing seedlings at the AFES and the FSL are described by Fowler (1980) and Nienstaedt (1979) respectively. One deviation, however, should be mentioned: At the FSL seedlings in the greenhouses were transplanted progressively to larger containers; at no time were they rootbound.

## RESULTS

Ten of the 17 attempts to cross white spruce and Himalayan spruce produced at least a few full seeds. The seven unsuccessful crosses occurred at the AFES in 1973 when Himalayan spruce pollen known to have low *in vitro* germination was used. Seed yields from both hybrid and control crosses were considerably higher at the FSL than at the AFES (table 1).

Germination of hybrid seeds was variable. Two AFES crosses failed to germinate; otherwise, the germination of hybrid seed was similar to that of comparable white spruce. The frequency of abnormal germination, e.g., seeds with reverse embryos, was higher among the hybrids than among the parental species. It was especially high for one cross (#7583) in which 15 of 38 germinants had reverse embryos.

Estimates of crossability, based on the yield of sound, germinable seed from crosses between two species, expressed as a percentage of the seed yield from within species crosses, provide a measure of relation between species (Critchfield 1973). However, for such estimates to be meaningful, comparable information should be available from intra- and interspecific crosses made on the same mother trees. Only six of the attempted crosses reported here meet this requirement. Crossability estimates based on these crosses range from 1.7 to 30 percent and average 9.1 percent (table 1).

The hybrid families can be distinguished from parental species on the basis of needle length and stem form and in some cases on the basis of number of cotyledons and needle serrulations. Variation in respect to hypocotyl color and foliage color is too great to be of diagnostic value, at least for young seedlings.

<sup>3/</sup>"Open" indicates open pollinated seed collected in native stands.

<sup>4/</sup>Seeds not germinated.

The hybrid seedlings are clearly distinguishable from white spruce (table 2).

The performance of hybrid families in respect to that of both parents or to white spruce alone was highly variable (table 2, 3). Seedlings from the two hybrid families from the 1971 pollinations at the AFES were smaller than seedlings of either parent species after 5 months in the greenhouse (table 2). After 2 years in the nursery, the hybrids and Himalayan spruce seedlings were somewhat taller than white spruce. However, the Himalayan spruce seedlings had lower survival (80 percent) than the hybrid and white spruces (100 percent) and showed winter damage, i.e., shoot tips killed back and desiccated needles. After 5 growing seasons in the field, all the Himalayan spruce seedlings had died and the hybrids had poorer survival (71 percent) than white spruce (94 percent). The hybrids showed winter damage and were shorter than white spruce.

After two growth cycles in the greenhouse, 15-month-old seedlings of hybrid family 2860 (1973 pollination, AFES) were intermediate in height between Himalayan (44 cm) and white spruce (34 cm). After 2 years in the nursery, the hybrids were shorter than either parent species. Six of the ten Himalayan spruce seedlings and one of the four hybrid seedlings suffered some winter damage. White spruce seedlings were undamaged.

The hybrids produced at the FSL generally performed better in terms of height growth than those produced at the AFES. Two of the three hybrid families were as tall or taller than the best white spruce

after 5, 10, and 19 months. The other hybrid family was shorter than the shortest white spruce family at 10 and 19 months. However, after one winter's exposure, all hybrids showed much winter damage.

## DISCUSSION

Our estimates of crossability for white x Himalayan spruce are tentative. Although the cross has been attempted on more than 17 different white spruces, all the Himalayan pollen came from a single non-native source (Brett Arboretum) and possibly from a single tree. It is highly probable that different Himalayan spruces used as either male or female parents would have yielded somewhat different estimates of crossability.

Attempts have been made to cross Himalayan spruce with eight other spruce species (and one hybrid), but apparently the species has never been used as female parent in any attempted crosses. In table 4, we have listed all recorded attempts to cross Himalayan and other spruce species as well as unpublished information on crosses made at the FSL. More detailed information is needed on the Hoffman-Kleinschmit crosses, some of which were made using mentor pollen. It appears that Himalayan spruce is closely related to white spruce, distantly related to *P. mariana* (Mill.) Brit., and only very distantly related to *P. abies* (L.) Karst. and *P. asperata* Mast. It is also probable that Himalayan spruce can be crossed with reasonable ease with other white spruce-related species, i.e., *P. engelmannii* (Parry) Engelm., *P. sitchensis* (Bong.) Carr., *P. jezoensis* (Sieb. et Zucc.) Carr.

<sup>1/</sup>Expressed as percent of *P. glauca* mean values.

<sup>2/</sup>Data recorded as percentages - therefore not converted.

<sup>3/</sup>"Open" indicates open pollinated seed collected in native stands.

<sup>4/</sup>This hybrid was not grown with other hybrids and white spruce. The value is computed using other *P. glauca* mean values.

At this time, the value of the hybrid, white x Himalayan, for direct use in reforestation is questionable. In eastern Canada, the hybrids have not performed as well as native white spruce. In Wisconsin, early growth of some hybrid families exceeds that of white spruce, but the hybrids are not adapted to the severe continental climate. However, they are promising enough to warrant further testing. Available hybrids should be vegetatively propagated and small tests outplanted in less extreme north temperate climates. At the same time, if possible, the cross should be repeated on a larger scale with pollen representing a wide array of Himalayan spruce provenances.

## ESTIMATING SITE INDEX IN EVEN-AGED NORTHERN HARDWOOD STANDS

PUBLIC DOCUMENTS  
DEPOSITORY ITEM

LIBRARY

Gayne G. Erdmann, *Research Forester,*  
and Ralph M. Peterson, Jr., *Research Technician,*  
North Central Forest Experiment Station,  
Marquette, Michigan

**ABSTRACT.** — Describes two methods for improving site index estimates in diffuse porous even-aged northern hardwood stands.

**KEY WORDS:** Stem analysis, diffuse, porous, *Acer saccharum* Marsh., *Acer rubrum* L., *Betula alleghaniensis* Britton.

Foresters need to know how good their land is for growing trees. They can estimate the quality of a site by measuring the heights and ages of the dominant and codominant trees on it.

Common practice has been to measure a tree's age with an increment core and its height with a hypsometer. This practice has been useful for estimating ages of conifers and ring porous hardwoods, but has often led to misleading or imprecise results in diffuse porous hardwoods because annual growth rings are more difficult to distinguish. Foresters can increase the accuracy of these estimates and eliminate age and height measurement errors by using a different technique, stem analysis.

Here, we explain how to use stem analysis to estimate the site quality for even-aged, second-growth northern hardwood stands. We describe the field and office procedures to use in developing height-age curves for a specific site. These curves provide the best estimates of the site's quality, because they are based on the past growth of trees there.

We also present an easy way to improve site estimates from existing site curves.

### DEVELOPING YOUR OWN TREE HEIGHT AGE CURVE

#### Select a Suitable Stand to Measure

Suitable stands are:

1. Even-aged with less than a 10-year age difference among the overstory trees (excluding residuals). Although stem analysis techniques can *only* be used to estimate site quality in even-aged stands, the information obtained can be applied to uneven-aged stands growing on comparable sites nearby.
2. Fully stocked with closed canopy.
3. Unaffected by excessive mortality caused by wind, insects, or disease; not disturbed by fire, grazing, or heavy thinnings from above since establishment.
4. At least 20 and preferably more than 50 years old measured at ground line. Site index estimates in younger stands are not as valid because of large variations in tree heights and growth rates in young stands.

5. Often composed of mixtures of hardwood species. The widely distributed sugar and red maples provide the best source of information for comparisons among northern hardwood species in the Lake States. However, when suitable maples are not present, reliable SI estimates can be obtained with other hardwood species.

6. At least 40 acres in size.

Choose high quality sample trees. They must be:

1. Dominants or strong codominants.
2. Above average diameter (considering all trees over 5 inches at breast height).
3. Single-stemmed — not from a sprout clump.
4. No more than 6 years old at breast height (free from evidences of past suppression).
5. Without serious insect, disease, and fire injuries. Don't use trees with rotten cores to

determine age unless all rings are still evident.

6. At least their own height away from the influence of residual trees.
7. Straight, without crooks or pronounced lean.
8. Clean-stemmed, without many epicormic branches, bumps, dead branch stubs, or other surface defects. A few small surface wounds, bark scrapes, and scars are acceptable.
9. Full-crowned, without dead tops or large forks. Small (1 inch in diameter) correcting forks are permissible.

## Fell, Measure, and Section Sample Trees

Horizontally mark selected trees (3 or more) at stump and breast height. Measure diameters and then record them on the stem analysis data form (fig. 1).

Figure 1.—Sample stem analysis data form.

1/ Disk ring count overlaps annual leader growth measurements below.

2/ Year 0 represents tree total height at ground line at the end of the 1979 growing season; tree heights for preceding years are obtained by subtracting annual leader growth values from the previous years total tree height.

Carefully undercut the trees above stump height and fell them to avoid tip breakage, hang-ups, and splitting. Remove all limbs. If any broken stem sections cannot be accurately joined together, discard the entire tree. Next, mark sectioning points at ground line, 1 foot, 4.5 feet, 9.3 feet, and then at 8-foot intervals up the stem (column 1). Measure total tree height to the nearest tenth of a foot and record it before sectioning the tree.

Measure down from the tree's tip between apical bud scars to find the annual height growth during the last 6 to 10 years; record on the same form (fig. 1). Take care in identifying bud scars beyond the sixth growth period where they may be obscured by diameter growth. Beginning as near the ground line as possible, cut 1- to 2-inch disks at each of the sectioning points. Cut high enough to overlap the measurements between apical bud scars. The overlapping section serves as a check on ages in plotting individual tree height-growth curves. Label (with red grease pencil or crayon) each disk according to the stand, tree, and sectioning height where it was taken. (A suitable label might be: 3-2-4.5—a disk sampled in stand 3 from tree number 2 at 4.5 feet above ground line.) Be sure to record tree location, date of sectioning, crew members, tree number, crown position (as dominant or strong codominant), species, and other pertinent soil information on the stem analysis form. If you desire, collect other information such as Girard form class, merchantable stem lengths, and diameters inside and outside bark for volume determinations.

## Counting the Rings

To help distinguish annual growth rings, use an electric planer or belt sander to smooth disk surfaces. Usually rings can be distinguished easily a few days after planing, but magnification, ample lighting, and staining (phloroglucinol in hydrochloric acid and Bismark brown stains) can be used to bring out growth rings on difficult disks. Record ring counts from disks taken at various sectioning points in column 3 on the stem analysis form (fig. 1). Count rings from the pith toward the perimeter of each disk and mark at 10-year intervals for easy checks. Take care to count every ring in periods of slow growth where they are closely spaced and avoid counting false (incomplete) rings.

## Make Tree Height-Age Curves

Make a height-age curve for each sample tree (fig. 2) by plotting measured height (column 1) over the corresponding age (column 2) from the stem analysis data (fig. 1). Height is the distance in feet above ground line to a particular sectioning point; age is the number of years required for the tree to reach that point (or

the difference between the tree's total age at ground line and the ring count (column 3) at that sectioning point). Then connect lines through the plotted height-age values for each sample tree height-age curve. Next compare the individual height growth patterns of all sample trees within the stand and discard trees that took more than 6 years to reach d.b.h. or that have grown irregularly because of top breakage or dieback.

After this, read heights at 5-year intervals and heights at the greatest common age from the height-age curves for each sample tree. Combine and average the data (table 1). Add a correction of one-half the average annual leader growth to each mean sectioning height to remove the bias caused by sectioning points not being cut exactly on the tips of terminal leaders. Obtain an average site index curve for your stand by plotting mean total height values over age values with the correction for bias added in table 1 and drawing a smooth freehand through the plotted values. Read your site index directly from the combined curve at index age 50 (65.0 in the example).

Some foresters prefer to fix d.b.h. height as the 0-age starting point, so they can save sample trees that suffered from early suppression but grew like free-growing trees after reaching breast height. This procedure brings all tree height-age curves to the same starting point. The average height-age curve is then determined and *then 4 years is added to the ring count at breast height to get total age.*

Figure 2.—Height-age curves and a combined curve for three red maple trees.

Table 1.--Red maple heights read from free hand sample-tree curves

(In feet)

| Tree number                                | Total height at age (years) |      |       |       |       |       |       |       |       |       |                    |                  |

<sup>1/</sup> Height at greatest common age.<sup>2/</sup> Height of oldest tree.<sup>3/</sup> A correction of 1/2 the average annual leader growth is added to each mean sectioning height to remove the bias caused by sectioning points not being cut exactly on tips of terminal leaders.<sup>4/</sup> No correction is needed because total height measurements were taken from the apical bud tip down the stem between annual terminal bud scars.

Ideally, foresters should compare stand yields from different areas at rotation age so they can maximize returns on their investments or at least be able to identify their most productive areas and work on them first. High quality northern hardwood saw logs can be produced in about 75 to 80 years in managed even-aged stands growing on good sites in the Lake States. It would be better to develop your own curves in stands near rotation age than to use Carmean's (1978) curves, which are based on reference age 50 and are most accurate for stands between 35 and 65 years old.

## DETERMINING SITE INDEX FROM EXISTING CURVES

Select 5 or more well formed trees from representative portions of older stands. Ten or more trees are needed in young (20- to 30-year-old) stands where growth is more irregular. Fell each sample tree carefully to avoid breaking the top or losing the tip. Measure the total tree height to the nearest foot. Cut a 1- to 2-inch cross-section (disk) from the tree at breast height and label it. Estimate total age by counting the rings on the disk and adding 4 years. Use Carmean's (1978) polymorphic site index curves to determine the

site index for each tree and then calculate an average site index estimate for the stand. You can use Carmean's (1979) site index comparisons for estimating site indices of other species.

PULPWOOD PRODUCTION<sup>1/</sup> IN THE LAKE STATES BY COUNTY, 1980

James E. Blyth, *Principal Market Analyst,*  
and W. Brad Smith, *Associate Mensurationist*

ABSTRACT.--Pulpwood production in the Lake States--Michigan, Minnesota, and Wisconsin--advanced to 5.66 million cords in 1980. Pulpwood production is shown by county and species group for these three States.

KEY WORDS: Residue, Michigan, Minnesota, Wisconsin.

Lake States pulpwood production climbed to 5.66 million cords in 1980. Wisconsin produced 2.36 million cords, Michigan 1.97 million cords, and Minnesota 1.33 million cords.

Nine out of 10 cords came from roundwood (including chips); the remainder came from mill residue such as slabs, edgings, veneer cores, and chips from these materials. Production from softwood and hardwood residue by State was:

|           | <u>Softwood</u>                    | <u>Hardwood</u> |
|-----------|------------------------------------|-----------------|
|           | (Hundred standard cords, unpeeled) |                 |
| Michigan  | 152                                | 1,380           |
| Minnesota | 339                                | 628             |
| Wisconsin | 395                                | 2,493           |

Principal species harvested were aspen (2,278,000 cords), pine (805,000 cords), maple (482,000 cords), balsam fir (322,000 cords), and birch (304,000 cords).

Wisconsin imported 30 percent of its pulpwood requirements, including 490,000 cords from Michigan, 216,000 cords from Minnesota, 170,000 cords from other (primarily western) States, and 92,000 cords from Canada.

<sup>1/</sup> Includes logs, bolts, and wood residue used in manufacturing particleboard and waferboard.

Counties cutting more than 100,000 cords were Delta, Marquette, Iron, and Menominee in Michigan; St. Louis, Koochiching, and Itasca in Minnesota; and Marinette, Oneida, Forest, and Price in Wisconsin. These counties furnished 36 percent of the pulpwood produced from roundwood in the Lake States in 1980.

<sup>1/</sup>Includes only those counties that supplied pulpwood in 1980.<sup>2/</sup>X=Less than 50 cords.

Pulpwood Production<sup>1/</sup> in the Lake States by County, 1981

James E. Blyth, Principal Market Analyst

and W. Brad Smith, Mensurationist

Abstract.--Lake States pulpwood production fell to 5.60 million cords in 1981. Pulpwood production is shown by county and species group in Michigan, Minnesota, and Wisconsin.

KEY WORDS: Residue, Michigan, Minnesota, Wisconsin

Pulpwood production in the Lake States--Michigan, Minnesota, and Wisconsin--dipped to 5.60 million cords in 1981: Wisconsin produced 2.39 million cords, Michigan 1.84 million cords, and Minnesota 1.37 million cords.

Ninety percent came from roundwood (including chips from roundwood); the remainder came from mill residue, such as slabs, edgings, veneer cores, and chips from these materials. Production from softwood and hardwood residue by State was:

| <u>State</u> | <u>Softwood</u>                       | <u>Hardwood</u> |
|--------------|---------------------------------------|-----------------|
|              | (Hundred standard cords,<br>unpeeled) |                 |
| Michigan     | 146                                   | 1,515           |
| Minnesota    | 387                                   | 615             |
| Wisconsin    | 466                                   | 2,440           |

Major species harvested were aspen (2,419,000 cords), pine (803,000 cords), maple (421,000 cords), balsam fir (309,000 cords), and birch (275,000 cords).

Wisconsin imported 26 percent of its pulpwood requirements, including 419,000 cords from Michigan, 177,000 cords from Minnesota, 164,000 cords from other (primarily western) States, and 75,000 cords from Canada.

<sup>1/</sup> Includes logs, bolts, and wood residue used in manufacturing particleboard, waferboard, and oriented strand board.

Counties cutting more than 100,000 cords were Delta, Menominee, Iron, and Marquette in Michigan; Koochiching, St. Louis, Beltrami, and Itasca in Minnesota; and Marinette, Oneida, Forest, Bayfield, Douglas, Price, and Sawyer in Wisconsin. These 15 counties contributed 44 percent of the pulpwood produced from roundwood in the Lake States in 1981.

Table 1.--Lake States pulpwood production from roundwood by county and species, 1981

(In hundred standard cords, unpeeled)

## TIMBER VOLUME IN NORTH DAKOTA COUNTIES, 1980

Thomas L. Castonguay  
*Associate Mensurationist*

**ABSTRACT.** — The second forest inventory of North Dakota shows growing-stock volume reaching 207 million cubic feet in 1980. Hardwoods make up more than 99 percent of this total.

**KEY WORDS:** Growing stock, sawtimber, softwoods, hardwoods.

North Dakota's 300,000 acres of commercial forest land supported 207 million cubic feet in growing-stock trees in 1980. Included in the total volume of growing stock are 510 million board feet of saw log material.

Additional volume in live rough, rotten, and short-log trees (nongrowing stock) is 89 million cubic feet.

Hardwoods make up more than 99 percent of the growing-stock volume North Dakota. Quaking aspen accounts for 29 percent of the total. More than 40

percent of the growing stock volume is in the elm-ash-cottonwood forest type (bottomland hardwoods).

North Dakota is divided into East and West inventory units. Eighty-six percent of growing-stock volume is in the eastern unit.

The sampling error of volume for the survey was  $\pm$  8.17 percent for 207 million cubic feet of growing stock in the State.

The second forest inventory of North Dakota was conducted in 1978 and 1979 by the North Central Forest Experiment Station with cooperation from the North Dakota Forest Service. Aerial photography was provided by the North Dakota Office of the Agricultural Stabilization and Conservation Service.

---

*Forests in which elm, ash, or cottonwood, singly or in combination, comprise a plurality of the stocking. Common associates include willow, sycamore, and maple.*

## FOREST AREA IN MICHIGAN, 1980

Arnold J. Ostrom  
*Mensurationist*

**ABSTRACT.**—In 1980 Michigan's forests covered 18.4 million acres, a decline of 5.2 percent from the 19.4 million acres reported in 1966. Commercial forest land dropped to 17.5 million acres.

**KEY WORDS:** Forest inventory, commercial forest land, noncommercial forest land.

One out of every 2 acres in Michigan is forested. These forested acres total 18.4 million acres in the State. Forest land covers more than four-fifths of the total land area in the Upper Peninsula, three-fifths of the land area in the northern half of Lower Michigan, but less than one-fifth of the land area in the southern half of the Lower Peninsula. Keweenaw County in the Western Upper Peninsula Unit is 97 percent forest, the most heavily forested county in the State (table 1).

Forest land Statewide declined one million acres or 5.2 percent between 1966 and 1980 inventories. A comparison of areas from the two inventories by geographical regions shows that the greatest reduction in forest area—almost 11 percent—occurred in the southern half of the Lower Peninsula (table 2).

Commercial forests (land suitable for growing crops of wood and not reserved from utilization) now occupy 17.5 million acres or 95 percent of Michigan's forest land. Since 1966, commercial forests have declined almost 1.4 million acres from 18.9 to 17.5 million acres a 7.3 percent reduction (table 3).

In looking at the State in sections, we can note the different rates of change in the commercial forest

land base (table 3). As with total forest land, the greatest reduction occurred in the Southern Lower Michigan Unit where commercial timber land decreased by 12.4 percent. In the Upper Peninsula commercial forest land decreased by 8.4 percent. The Northern Lower Michigan Unit had the smallest decrease—3.7 percent or 260 thousand acres (table 3).

Only 5 percent or 879,000 acres of Michigan's forests are classified as noncommercial. Of this, 622,000 acres are productive forest land, but reserved for uses other than timber production such as parks and other reserved recreation areas. The remaining 257,000 acres are forest land too poor to grow timber crops. The 363,000-acre increase in noncommercial forest land between inventories is the result of additions to the productive reserved forest base (table 4). These additions primarily include National Lakeshore Areas, State Parks, State Sharptail Grouse Management Areas, and State Recreation Areas.

The sampling error for the 17.5 million acres of commercial forest area for this inventory was  $\pm .33$  percent.

This forest inventory was conducted by the North Central Forest Experiment Station. More intensified field sampling was made possible by additional funding and personnel provided by the Michigan Legislature through the State's Department of Natural Resources and by interested forest industry companies.

<sup>1</sup>1970 Bureau of the Census estimates.

<sup>2</sup>Land at least 16.7 percent stocked by forest trees of any size, or formerly having such tree cover; excludes land currently developed for nonforest use such as urban or heavily settled residential or resort area, city parks, orchards, improved roads, or improved pasture land. The minimum forest area classified was 1 acre. Classified as forest were roadside, streamside, and shelterbelt strips of timber with a crown width of at least 120 feet and unimproved roads and trails, streams, and clearings in forested areas if less than 120 feet wide.

<sup>3</sup>Unproductive forest land incapable of yielding crops of industrial wood because of adverse site conditions, and productive public forest land withdrawn from commercial timber production through statute or administrative regulation.

<sup>4</sup>Forest land producing or capable of producing crops of industrial wood and not withdrawn from timber utilization by statute or administrative regulation.

LIBRARY

**ABSTRACT.**—The fourth inventory of Michigan's forest resources shows a 27 percent increase in growing-stock volume between 1966 and 1980, from 15.0 to 19.1 billion cubic feet.

**KEY WORDS:** Timber resource, statistics, growing stock, sawtimber.

Volume of growing stock<sup>1</sup> on commercial forest land in Michigan increased from 15.0 billion cubic feet in 1966 to 19.1 billion cubic feet in 1980, a 27 percent gain:

| Growing stock | Survey year |        |
|---------------|-------------|--------|
|               | 1966        | 1980   |
| Softwoods     | 4,001       | 5,356  |
| Hardwoods     | 11,049      | 13,748 |
| Total         | 15,050      | 19,104 |

Softwood growing stock volume increased by 34 percent while hardwood volume grew by 24 percent.

These volume gains were made despite a 7.3 percent decline in commercial forest area. These increased volumes reflect an increase in average growing-stock volume per acre from 798 cubic feet per acre in 1966 to 1,092 cubic feet per acre in 1980.

Growing stock volume did not increase uniformly throughout the State (table 1). The largest total volume and greatest percent increase were in the Northern Lower Peninsula Unit, and the smallest percent gains were in the Eastern Upper Peninsula (fig. 1).

The hard maple species group, primarily sugar maple, is the most abundant species group in Michigan and accounts for more than 14 percent of the growing-stock volume. Its volume increased by 20 percent between surveys. Aspen, the second most plentiful species group in the State, makes up another 14 percent. The soft maple group, primarily red maple, is the third most abundant species in Michigan and showed a dramatic increase of 78 percent in growing-stock volume between inventories. As shown in the following tabulation other prominent species include the oak and pine groups:

| Species group   | Growing stock<br>(Million cubic feet) |
|-----------------|---------------------------------------|
| Hard maple      | 2,749                                 |
| Aspen           | 2,617                                 |
| Soft maple      | 2,253                                 |
| Oak             | 2,019                                 |
| Pine            | 1,886                                 |
| Other hardwoods | 4,110                                 |
| Other softwoods | 3,470                                 |
| Total           | 19,104                                |

<sup>1</sup>Net volume in cubic feet of growing stock trees 5 inches d.b.h. and larger from the stump to a variable 4-inch top diameter.

<sup>2</sup>Figures have been adjusted from those published after the 1966 survey to conform to 1980 volumes because of changes in survey procedure and definitions.

Table 1.--Net volume of growing stock in 1966 and 1980 by Forest Inventory Unit and Change Since 1966, Michigan

| Forest Inventory Unit    | 1966 Growing-stock volume | 1980 Growing-stock volume | Change since 1966 |
|--------------------------|---------------------------|---------------------------|-------------------|
|                          | Million cubic feet        |                           | Percent           |
| Eastern Upper Peninsula  | 3,403                     | 4,035                     | +19               |
| Western Upper Peninsula  | 4,757                     | 5,785                     | +22               |
| Northern Lower Peninsula | 4,945                     | 6,825                     | +38               |
| Southern Lower Peninsula | 1,945                     | 2,459                     | +26               |
| <b>Total</b>             | <b>15,050</b>             | <b>19,104</b>             | <b>+27</b>        |

Included in the growing stock volume are 47.7 billion board feet of sawtimber.<sup>3</sup> As with growing stock, hard maple leads other species groups in volume. We then find a slightly different order from growing stock for the other prominent sawtimber species, with the oak group second, pine third, and aspen and soft maple rounding out the top five:

| Species group   | Sawtimber<br>(Million board feet) <sup>4</sup> |
|-----------------|--|
| Hard maple      | 6,998  |
| Oak             | 6,626  |
| Pine            | 5,798  |
| Aspen           | 5,303  |
| Soft maple      | 4,813  |
| Other hardwoods | 9,983  |
| Other softwoods | 8,148  |
| <b>Total</b>    | <b>47,669</b>                                  |

The major concentrations of timber are found in the Upper Peninsula:

| Forest inventory unit    | Growing-stock volume<br>(Million cubic feet) |               |
|--------------------------|--|---------------|
|                          | Softwoods                                    | Hardwoods     |
| Eastern Upper Peninsula  | 1,748  | 2,287         |
| Western Upper Peninsula  | 1,729  | 4,056         |
| Northern Lower Peninsula | 1,707  | 5,118         |
| Southern Lower Peninsula | 172  | 2,287         |
| <b>Total</b>             | <b>5,356</b>                                 | <b>13,748</b> |

<sup>3</sup>Net volume of the saw log portion of live sawtimber trees (softwoods 9.0 inches d.b.h. or larger and hardwoods 11.0 inches d.b.h. and larger) from the stump to a point in the central stem at which utilization for sawn products is limited by large branches, forks, or other defects, or by a diameter outside bark 7.0 inches for softwoods and 9.0 inches for hardwoods.

<sup>4</sup>International -inch rule.

This area contains less than 30 percent of the State's land area but more than 50 percent of its growing-stock volume. Marquette County, in the Upper Peninsula, has the most growing-stock and sawtimber volume of any county in the State (tables 2 and 3). Sugar maple and lowland conifers are well represented in this part of the State. The Northern Lower Peninsula Unit contains an additional 36 percent of the State's volume. This area contains more than 50

Figure 1.—Michigan's four Forest Inventory Units.

percent of the pine growing-stock volume and 57 percent of the oak growing-stock volume in the State.

The sampling error was  $\pm 0.7$  percent for the 19.1 billion cubic feet of growing stock material in the State.

This forest inventory was conducted by the North Central Forest Experiment Station. More intensified field sampling was made possible by additional funding and personnel provided the North Central Station by the State Legislature through the Michigan Department of Natural Resources and by interested forest industry companies.

Table 2.--Net volume of growing stock on commercial forest land by species groups and county, Michigan, 1980

(In thousand cubic feet)

| County                   | EASTERN UPPER PENINSULA |                |                       |                      |                 |                  |                  |                |                  |                  |

CLEMSON  
LIBRARY

**ABSTRACT.**—In 1980 eastern South Dakota's forest resources covered 266,300 acres of land, a slight decline from the 296,600 acres reported in 1965. The area of commercial forest land also dropped from 165,400 acres to 113,600 acres. The elm-ash-locust forest type covers 40 percent of the commercial forest area.

**KEY WORDS:** Commercial forest land, productive-reserved, unproductive, wooded strips, shelterbelts, nonforest with trees, forest type, land use.

One out of every 157 acres in South Dakota east of the 103rd meridian is forested—a total of 266,300 acres.<sup>2</sup> Most of the forest area is along the Grand, Missouri, Belle Fourche, Big Sioux, Cheyenne, and Big White Rivers. An area of 113,600 acres, 43 percent of the total forest area, is suitable for producing timber crops and is classified as commercial forest land.<sup>3</sup> The elm-ash forest type is most prevalent, growing on 40 percent (45,400 acres) of the commercial forest area. The ponderosa pine forest type covers an additional 16 percent or 17,800 acres:

| Forest type      | Area           |                |
|------------------|----------------|----------------|
|                  | 1965           | 1980           |
| Ponderosa pine   | 24,100         | 17,800         |
| Oak              | 7,400          | 4,500          |
| Elm-ash          | 62,100         | 45,400         |
| Cottonwood       | 42,000         | 18,500         |
| Plains hardwoods | 22,000         | 13,000         |
| Nonstocked       | 7,800          | 14,400         |
| <b>Total</b>     | <b>165,400</b> | <b>113,600</b> |

The most heavily forested county in eastern South Dakota is Shannon County, which has 20,100 acres of commercial forest—1.5 percent of the land area (Table 1).

Forest land declined in eastern South Dakota by 24,300 acres or 8 percent between 1965 and 1980. Commercial forest land decreased 31 percent during the same period.

| Land use            | 1965<br>(Thousand acres) | 1980     | Change since 1965<br>(Percent) |
|---------------------|--------------------------|----------|--------------------------------|
| Forest              |                          |          |                                |
| Commercial          | 165.4                    | 113.6    | - 31                           |
| Noncommercial       |                          |          |                                |
| Unproductive        | 125.2                    | 147.4    | + 18                           |
| Productive-reserved | —                        | 5.3      | —                              |
| Total forest        | 290.6                    | 266.3    | - 8                            |
| Nonforest           | 41,712.5                 | 41,441.9 | - 1                            |
| Total land          | 42,003.1                 | 41,708.2 | - 1                            |

<sup>1</sup>This report covers the area east of the 103rd meridian. Western South Dakota will be inventoried by the Intermountain Forest and Range Experiment Station.

<sup>2</sup>The sampling error for eastern South Dakota's commercial forest area was  $\pm 12.8$  percent per million acres of commercial forest land, or  $\pm 38$  percent for the entire Unit area of 113,600 acres.

<sup>3</sup>Commercial Forest Land.—Forest land that is producing or is capable of producing crops of industrial wood and not withdrawn from timber utilization by statute or administrative regulation.

Published 1965 areas have been adjusted to align the estimates more closely with definitions of land classification and procedures used in the 1980 survey.

Noncommercial forest land totaled 152,700 acres in 1980. The productive-reserved<sup>4</sup> area increased from none in 1965 to 5,300 acres in 1980. This land is located in the Badlands National Monument in Pennington and Shannon Counties. The remaining area of noncommercial forest land is unproductive forest land, too poor to grow timber crops. The unproductive forest land is concentrated in the Badlands area.

<sup>4</sup>Land sufficiently productive to qualify as commercial forest land but withdrawn from timber utilization through statute or administrative designation, or through exclusive use for Christmas tree production as indicated by annual shearing.

Not included in the forest land area, but an important resource in eastern South Dakota are the 287,800 acres of natural and planted wooded strips and shelterbelts. This area includes windbreaks around farm buildings and other structures.

This information on forest land wooded strips, and shelterbelts is part of the results of the third eastern South Dakota forest, made by the North Central Forest Experiment Station during 1979-1980. Other publications giving further details will be available soon.

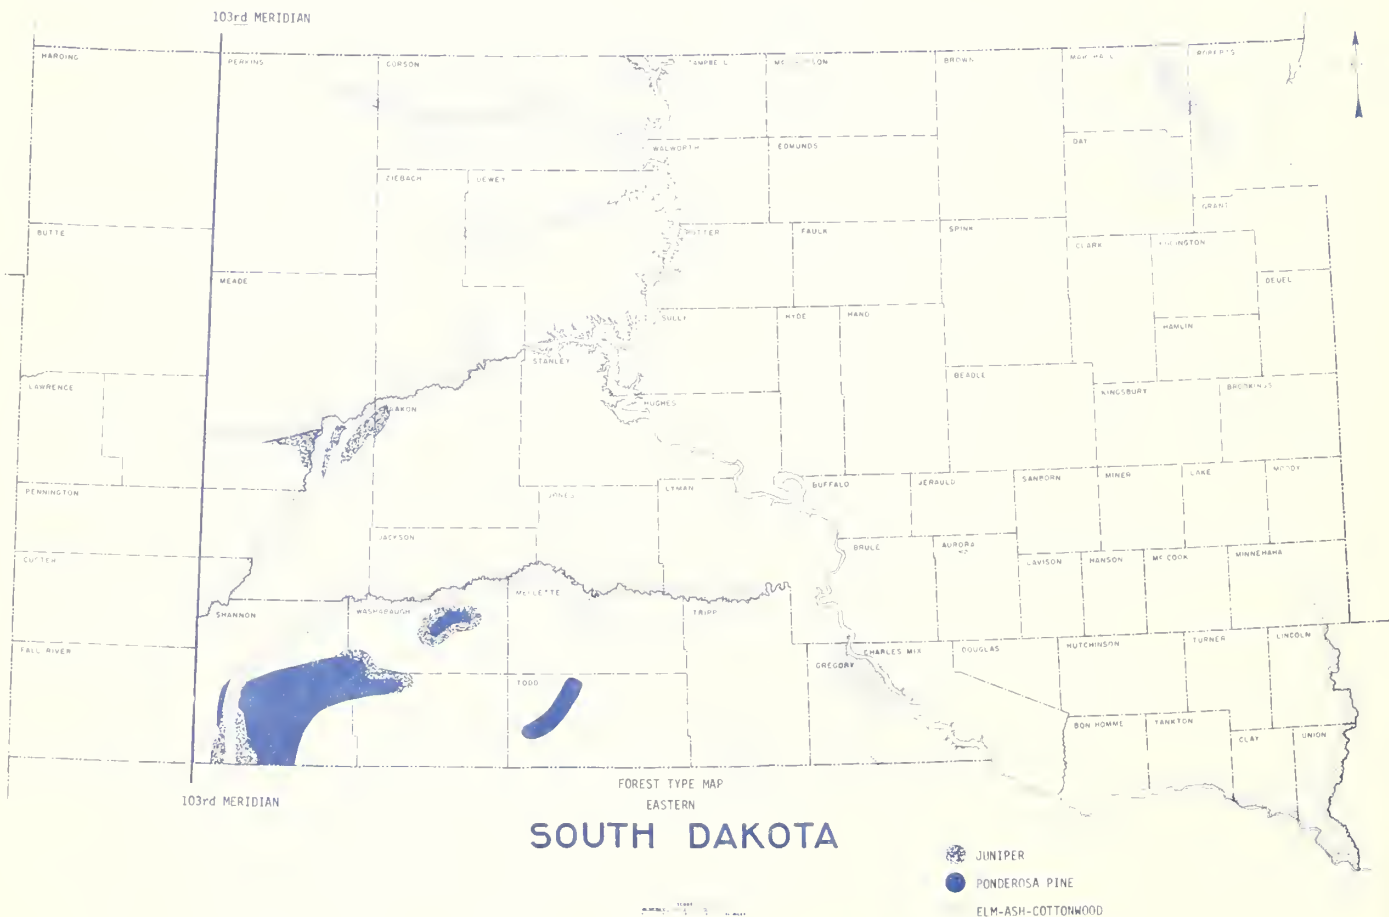

Figure 1. —Forest area in eastern South Dakota.

Table 1.--Area of land, forest land, and nonforest land with trees, by county, eastern South Dakota, 1980

| County                 | All <sup>1</sup> / land |   | Forest land <sup>2</sup> /  |                           | Nonforest land with trees <sup>6</sup> / |   |   |                |

<sup>1/</sup>1980 Bureau of Census estimates. Includes: Forest, nonforest with trees, and nonforest without trees.

<sup>2/</sup>Land at least 16.7 percent stocked by forest trees of any size, or formerly having such tree cover, excludes land currently developed for nonforest use such as urban or heavily settled residential or resort areas, city parks, orchards, improved roads or improved pasture land. The minimum forest area classified was 1 acre. Classified as forest were roadside, streamside, and shelterbelt strips of timber with a crown width of at least 120 feet. Unimproved roads and trails, streams and clearings in forest areas were classed as forest if less than 120 feet wide.

<sup>3/</sup>Land sufficiently productive to qualify as commercial forest land but withdrawn from timber utilization through statute or administrative designation, or exclusive use for Christmas tree production as indicated by annual shearing.

<sup>4/</sup>Forest land incapable of producing 20 cubic feet per acre per year of industrial wood under natural conditions, because of adverse site conditions, i.e., sterile soils, dry climate, poor drainage, high elevation, steepness, and rockiness.

<sup>5/</sup>Forest land producing crops of industrial wood and not withdrawn from timber utilization by statute or regulation.

<sup>6/</sup>Areas of land with trees but with less than 16.7 percent stocking and/or are less than 120 feet wide i.e., cropland with scattered trees, improved pasture with scattered trees, wooded strips, windbreaks, and idle farmland with scattered trees.

<sup>7/</sup>An acre or more of continuous forest land that meets the definition of commercial forest land except that it is less than 120 feet wide.

<sup>8/</sup>A group of trees less than 120 feet wide and used for the protection of soil and croplands.

<sup>9/</sup>An acre or more containing at least one tree 5.0 inches in diameter, but having less than 16.7 percent stocking.

<sup>10/</sup>That portion of the county east of the 103rd meridian.

# DIAMETER GROWTH, SURVIVAL, AND VOLUME ESTIMATES FOR MISSOURI TREES

MAR 25 1983

Stephen R. Shifley, *Research Forester,*  
and W. Brad Smith, *Research Forester*

CLEMSON  
LIBRARY

**ABSTRACT.**—Measurements of more than 20,000 Missouri trees were summarized by species and diameter class into tables of mean annual diameter growth, annual probability of survival, net cubic foot volume, and net board foot volume. In the absence of better forecasting techniques, this information can be utilized to project short-term changes for Missouri trees, inventory plots, stands, or forests.

**KEY WORDS:** Cubic foot volume, board foot volume, crown class, mortality.

North Central Forest Experiment Station researchers are assembling the data necessary to develop a system of growth and mortality simulation models for the Central States similar to those used for the Lake States species in the Stand and Tree Evaluation and Modeling System (STEMS).<sup>1</sup> Much of the data for this research has come from Missouri. In fact, nearly 3,000 forest inventory plots were measured when Missouri's forests were surveyed in the early 1970's (Spencer and Essex 1976). Two thirds of those plots were remeasurements of plots established in 1959.<sup>2</sup> These plots include data for more than 20,000 trees in Missouri.

<sup>1</sup>Belcher, D. M.; Holdaway, M. R.; Brand, G. J. *A description of STEMS, the Stand and Tree Evaluation and Modeling System (in prep.)*.

<sup>2</sup>Includes 226 plots from the Mark Twain National Forest that were established in 1971 and remeasured in 1977.

The large quantity and wide distribution of the Missouri data make them of special interest as a source of individual-tree growth, mortality, and volume information. Summarized here is information concerning mean annual diameter growth, mean annual survival rate, and mean cubic-foot and board-foot volume by species group and diameter class. In the absence of more sophisticated techniques, these summaries are useful guides for estimating growth, mortality, and volume for Missouri trees and stands.

The summary of diameter growth by species group and diameter class (table 1) shows that mean annual diameter growth rates ranged from well below 0.1 inch (0.3 cm) per year for hickory to more than 0.3 inch (0.8 cm) per year for cottonwood. The mean annual diameter growth for all trees was 0.115 inch (0.292 cm). Averaged across all species, diameter growth increased with increasing diameter, but this trend was not consistent for each species group individually. Some of the variation in the diameter growth rates both among and within species groups is due to the different number of observations and different sampling error associated with each of the mean values reported. Summaries of diameter growth by crown class, diameter class, and species group clearly show the faster growth associated with trees from dominant and codominant crown classes (table 2).

The mean annual survival rate for the sampled trees was 98.4 percent (table 3). Mean annual sur-

vival rates were generally lower for trees less than 5 inches in diameter or greater than 15 inches in diameter than they were for trees 6 to 14 inches in diameter.

Net cubic-foot and board-foot volumes by species group and diameter class were averaged from more than 13,000 individual tree observations (tables 4 and 5). Gross tree volumes were calculated using Stone's equation<sup>3</sup>, which is a function of observed breast height diameter, merchantable height, and top diameter outside bark. Gross volume estimates were corrected for differences in bark thickness among species; field estimates of cull volume were applied to these gross volume estimates to arrive at net tree volume.

Minimum acceptable top diameters outside bark were 4.0 and 9.0 inches for poletimber and sawtimber, respectively. However, poor form often lowered merchantable height below where the minimum top diameter occurred, so top diameters at merchantable height generally increased as diameter increased.<sup>4</sup>

Tables 1-5 can be used to estimate average tree-by-tree growth and survival for Missouri inventory plots. Such projections require a tree list that itemizes species, diameter, and perhaps crown class for a representative sample of trees from the stand or stands being considered. Alternatively, total stand growth can be estimated using the stand table projection techniques described by Husch *et al.* (1972). Stand table projections require a summary of the number of trees by species and diameter class.

Although simple inventory projections can be implemented using only a pencil, some paper, and a hand calculator, they are also readily computerized. For example, Moser (1980), Mawson and Mack (1980), Harrison and Rauch (1979), Pelz (1978), and Ek *et al.* (1973) all describe computerized forest data processing programs that summarize current and projected stand and stock tables from forest inventory

---

<sup>3</sup>A description of this function can be found in the appendix of: Raile, Gerhard K.; Smith, W. Brad.; Weist, Carol A. *A Net volume equation for Michigan's Upper and Lower Peninsulas. Gen. Tech. Rep. NC-80. St. Paul, MN: U.S. Department of Agriculture, Forest Service, North Central Forest Experiment Station; 1982. 12 p.*

<sup>4</sup>Tables of associated gross merchantable volumes, merchantable heights, and merchantable top diameters are available from the authors.

data. Growth estimates in those programs are usually derived from increment cores taken during the inventory or from user-supplied growth-rate tables. A similar system could be adapted for use in Missouri with the data in tables 1-3 providing the basis for estimating growth and mortality. Increment core measurements could be used to adjust the growth rate tables to reflect local conditions.

For any of the above projection techniques, tree and stand volume can be estimated from tables of mean tree volume (tables 4 and 5). Or, if all the necessary information were available, local volume equations, such as those prepared for Missouri by Hahn (1975) could be used.

When using the information in tables 1-5, remember that all reported values are averages that are subject to variability and that some average values are based on very few observations. Furthermore, these values do not account for the effects of site quality, stand density, or stand manipulation on growth. Projections for a period much longer than the 11-year span encompassed by the basic data would be of questionable reliability. We anticipate that when the data from Missouri are merged with similar information from other Central States, it will be possible to formulate and calibrate a system of STEMS-type growth and mortality models applicable both in Missouri and in surrounding States. Such models would account for site quality, stand density, and inter-tree competition to provide more accurate and more biologically realistic projections of tree and stand growth than are possible from the information reported here.

<sup>1</sup>Growth rates were calculated using as many observations as were available; some rates are based upon one observation. Growth rates for each diameter class larger than 20 inches were usually computed using fewer than 2 percent of the total number of observations for a given species group.

<sup>2</sup>Indented entries designate individual species within a group that have 100 or more observations. Entries for the total species group are not indented and they include data for all species in that group regardless of whether information for one or more of the individual species in the group is reported separately.

Table 2.--Mean annual diameter growth by species group, crown class, and diameter class, Missouri<sup>1</sup>

(In inches)

| Species group                    | Crown class  | Number of observations | Diameter class (inches at breast height) |         |         |         |          |           |           |           |           |           |           |           |           |            |      |      |      | Average all classes |
|----------------------------------|--------------|------------------------|--|---------|---------|---------|----------|-----------|-----------|-----------|-----------|-----------|-----------|-----------|-----------|------------|------|------|------|---------------------|

## AIR DRYING OF CHUNKWOOD AND CHIPS

Joseph B. Sturos, *Mechanical Engineering Technician,*  
Lynne A. Coyer, *Industrial Engineering Technician,*  
and Rodger A. Arola, *Principal Mechanical Engineer,*  
Houghton, Michigan

**ABSTRACT.**—A new method of comminuting wood has resulted in a new wood particle form called chunkwood, which is much larger than the common pulp-size chip. Chunkwood appears well suited for use as a fuel but nothing is yet known about its storage, drying, or combustion characteristics. This paper reports on two exploratory drying experiments we conducted to see whether chunks, with their much larger interparticle voids, dry more readily than chips. In one experiment we used natural convective ambient air to dry chunks and chips and found that chunks dried much faster than chips. In another experiment we used forced ambient air to dry chunks and chips and found that chips dried faster than chunks. However, the chunks offered much less resistance to forced air flow and thus required less fan energy. We recommend that larger, more controlled studies be undertaken to further document the ambient drying characteristics of chunkwood as compared to chips.

**KEY WORDS:** Energy wood, fuel, moisture content, biomass for energy, fuel enhancement, fuel characteristics.

Today wood is increasingly used for generating industrial energy—mainly process steam and heat. The principle source of energy wood has been mill residues. But recently, whole-tree chips have been gaining in use mainly because they are readily available in large quantities due to the commercial introduction and widespread use of whole-tree portable

chipping machines. Although conventional whole-tree chips can be successfully combusted in solid fuel boilers, they are not necessarily the most desirable form for wood as a solid industrial fuel. For example, they tend to have high solid particulate emissions because of the high flue gas velocities when burned in industrial scale combustors. Additionally, chips tend to layer and thereby restrict the flow of under-fire combustion air. Pulp-size chips also cause bridging problems, require considerable energy to produce, have a low bulk density, and layer closely when stored in piles and thus restrict the movement of air necessary for natural drying. This lack of venting in chip piles also contributes to heat build-up and fire danger.

In conjunction with harvesting operations, we have explored ways to comminute small diameter trees and logging residue into particles suitable for ring flaking for flakeboard production or for use as a solid fuel. As a result of this research, two different types of machine have been developed that produce “chunks” of wood that appear well suited for either use (Arola *et al.* 1982, Arola *et al.* in prep., Barwise *et al.* 1977, Barwise *et al.* 1982). The resulting chunks are much larger, require less energy to produce, and have somewhat greater bulk density than conventional pulp chips. They also exhibit entirely different bulk-ing characteristics because of their chunky and irregular shape.

In a pile or thick layer of this material, large void spaces exist between particles. It was our belief that these chunks, with large interparticle voids, would dry faster and generate less solid particulate emissions when burned than conventional wood chips. However, because these chunks are a new particle form, information is not available on their storage, drying, or combustion characteristics. Our work in chunkwood production and drying is the beginning foundation.

For use as a solid fuel, any amount of drying prior to combustion is advantageous. Therefore, the purpose of our study was to determine drying rate differences between chunked wood and conventional pulp-size chips under ambient air test conditions.

## METHODS

We established two simple drying experiments using ambient room air (drawn from within our seasonally heated machine shop building) to compare these new potential fuelwood chunks and conventional pulp-size chips. The first experiment used natural convective air drying while the second experiment used forced air convective drying. In these experiments we used wood from both aspen and red maple. The chips were made using a Morbark "Chip-Pac"<sup>1</sup> Model 3-48 chipper set to produce 3/4-inch long standard pulp chips. The chunks were made on our experimental chunking machine. From independent tests with the machine, we found that chunks ranged from 2 to 5 inches, and averaged 3.5 inches long. Particle cross sections ranged from about 1/2 inch up to the full diameter of the bolts being chunked (Arola *et al.* 1982).

In the natural convective air drying experiment, equal volumes of green chunks and chips were placed in separate 3.6 ft<sup>3</sup> (one-half of a 55-gallon barrel) cylindrical containers, set out in an open room, and allowed to freely dry (fig. 1). Initial tare and sample weights were determined. The green wood weights initially ranged between 60 and 85 pounds. To monitor moisture loss, both containers were periodically weighed. Because of time and space limitations and the preliminary nature of our study, the test was repeated only once, by species. Therefore, our results are not based on replications.

<sup>1</sup>The use of trade, firm, or corporation names in this publication is for the information and convenience of the reader. It does not constitute an official endorsement or approval of any product or service by the United States Department of Agriculture to the exclusion of others that may be suitable.

Figure 1.—Test setup for natural convective drying of chips (left) and chunks (right).

In the second experiment using forced air convective drying, we devised a test apparatus so that a known quantity of green chips or chunks could be dried by forcing ambient air through the particles. To begin, a 7.3 ft<sup>3</sup> cylindrical container (standard 55-gallon barrel) with a screened bottom insert was filled with chips, weighed, and set on a 7.5 hp variable volume blower system. The blower's inlet restrictor was adjusted to give a nominal 340 cfm of air flow through the filled barrel (fig. 2). The 340 cfm level was chosen because it was the lowest practical level at which this particular blower system would operate and not because it was optimum for drying. As the particle drying progressed, the following data were periodically noted: chip weight; elapsed time; air flow rate; pressure drop through the chips; ambient air temperature and relative humidity; and atmospheric pressure. We also determined beginning and ending moisture content. After the barrelful of chips was dried, an equal weight of chunks was dried following the same procedure. For this series of tests, five repetitions were made for each species using uncontrolled ambient room air. In all cases, we terminated the drying tests when the weight loss stopped or the drying rate was so slow that it was judged impractical to continue.

The aspen tests were run from the end of March until the end of May; the ambient air temperature averaged 73° F, and the relative humidity averaged 32 percent. The red maple tests were run between early June and early August. The ambient air temperature averaged 75° F, and the relative humidity averaged 60 percent.

Figure 2.—Test setup for forced air convective drying.

For both experiments, we determined and plotted average moisture contents (wet weight basis).

In our second test series we calculated the energy used (power x time) based on the air horsepower dissipated within the wood bed. We calculated air horsepower from the equation (McDonald *et al.* 1967):

$$\text{Air hp} = 0.0001575 pQ$$

where  $p$  = pressure drop across the wood bed in inches of water and  $Q$  = air flow rate in  $\text{ft}^3/\text{min}$ .

## EXPLORATORY RESULTS

In our natural convective air drying tests, we observed that the chunks dried much faster and to a lower moisture content than the chips for both species (fig. 3). This finding supports our belief that chunks dry faster than chips under natural convective air drying. (Conclusive data should be developed under conditions of controlled temperature and humidity.) Though unsubstantiated, we attribute the marked difference between drying rates of chunk-wood and chips to the bulky character of the chunk-wood, which gives larger air spaces (voids) and al-

Figure 3.—Time required for natural convective drying of aspen and red maple chunks and chips.

lows for easy air flow, as opposed to the flat character of chips, which layer closely and restrict air movement and trap moisture. We observed that at the end of our natural convective air drying tests, when the chips and chunks were emptied from the containers, the chunk container was completely dry while the chip container was rusty and wet. For the red maple (run during the more humid summer months), we actually found standing water at the bottom of the chip barrel.

In our forced air experiments, we found that the chunks dried slower than the chips (fig. 4); however, the pressure required to force the air through the chunks was much less than for the chips—consequently, the energy required was much less (fig. 5). These differences again are attributed to the chunks' larger interparticle void spaces, which offer much less resistance to air movement. In commercial practice, this energy advantage could possibly offset the added cost of the larger drying bin that would be required to give the same production rate (pounds of dry wood per hour) as for chips.

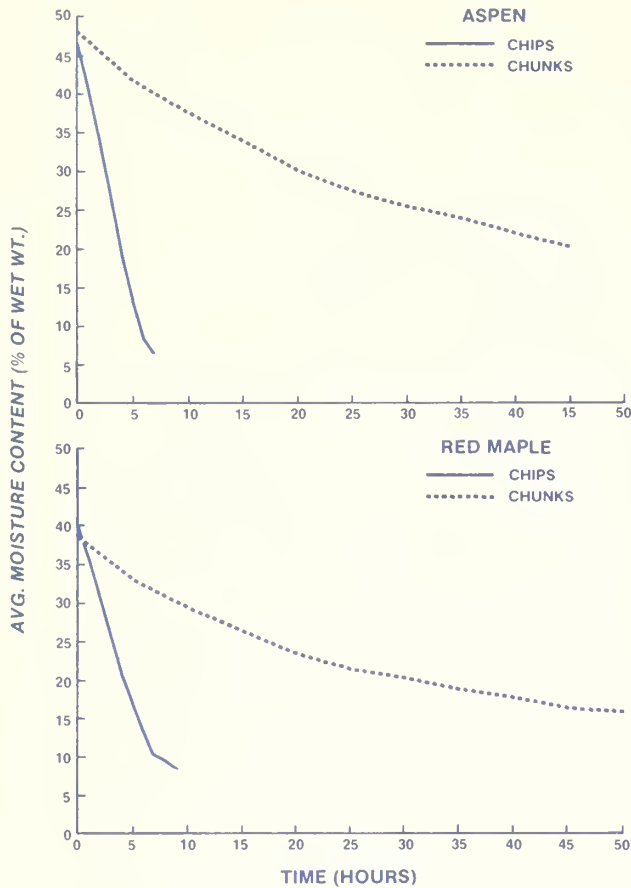

Figure 4.—Time required for forced air convective drying of aspen and red maple chunks and chips. The curves represent the average of five repetitions.

Figure 5.—Energy required for forced air convective drying of aspen and red maple chunks and chips. The curves represent the average of five repetitions.

We recognize the statistical limitations of our observations—particularly due to our inability to precisely control temperature and relative humidity. Nonetheless, we feel that this exploratory investigation has indicated that chunks have better drying characteristics than pulp-size chips. Based on our preliminary results, we recommend that more controlled investigations be conducted on a larger scale using ambient air drying of chunks in free-standing piles and in a silo with low velocity forced air.

## A BUDGET TREE IMPROVEMENT PROGRAM

**Hans Nienstaedt**, *Chief Plant Geneticist,*  
and **Hyun Kang**, *Population Geneticist,*  
*Rhineland, Wisconsin*

**ABSTRACT.**—In an Upper Peninsula Michigan test of simple design, white spruce of a Beachburg, Ontario provenance grew 17.5 percent taller than white spruce from the Ottawa N.F. The paper describes how to convert such tests to low-cost, low-risk, highly flexible improvement programs. The approach is applicable to other species of low priority.

**KEY WORDS:** White spruce, Lake States region, genetic gains, seed production areas, multigeneration breeding.

We will describe a low-cost alternative to tree improvement in a defined area such as a seed collection zone or a breeding zone. We will use a simple white spruce test as an example.

White spruce from SE Ontario performs well over a large region in north-central and north-eastern United States and adjacent Canada. Five Ontario sources of seed have been particularly mentioned: Douglas (King and Rudolf 1969), Peterborough (Teich 1970), Beachburg (Nienstaedt 1969, Genys and Nienstaedt 1979, Wright *et al.* 1977), Maple Leaf (Stellrecht *et al.* 1974), and Cobourg (Fowler and Coles 1977).

In most seed-source tests in the Lake States, the SE Ontario seedlings have been among the best performers and have been superior to seedlings of the local seed source. In a Minnesota test (Stellrecht *et al.* 1974), the Maple Leaf seedlings grew 17.5 percent higher 15 years after plantation establishment than the best of three control populations; this translated

into a 41.5 percent advantage in tree volume. The Ontario-source trees were 76 and 169 percent taller than those in the other two control populations.<sup>1</sup>

Fowler and Coles (1977) have described a program to develop a source of Ottawa River Valley seeds in the Maritimes. Their plan is based on progeny testing with early roguing in the nursery and field test. We suggest a simple and cheaper approach; we believe the method can and should be used for other species as well.

## MATERIALS AND METHODS

Beachburg, Ontario seedlings were raised with Ottawa N.F. stock at the Watersmeet, Michigan nursery. Standard nursery procedures were used and 2-2 stock was planted in May 1968 in an open field near Trout Lake, Michigan, approximately 24 miles NNW of St. Ignace. At the time of planting the sod cover was heavy so a sod scalper was used to prepare the ground. Trees from the two populations were planted in alternate rows at an approximate 6 x 8 foot (1.8 x 2.4 m) spacing. There was a total of 94 NS rows with about 140 trees per row. In September 1970 the survival was 97 percent.

<sup>1</sup>The controls involve standard nursery stock—two populations from State nurseries and one from an industrial nursery. The sources of seed are unknown but are presumably from Minnesota.

In October 1981, when the trees were 18 years old, total heights were measured. The sampling was as follows: Pairs of trees—one tree from Beachburg and one from Ottawa in adjacent rows—were measured. We began with the first 4 pairs in row #2 (Beachburg) and #3 (Ottawa) in the SE corner of the planting. Pairs 5-8 were in rows #4 and #5, pairs 9-12 in rows #6 and #7 and so forth on a diagonal from the SE corner of the planting towards the north. When the north edge of the planting was reached, we moved across the rows to the east and again began one row in from the edge of the planting and then proceeded diagonally across the planting towards the southwest. The sampling involved the eastern third of the planting. A total of 232 pairs of trees was measured.

## RESULTS

The Beachburg, Ontario trees were the best with a mean height of 3.52 m (11.5 feet)  $\pm$  1.02 m (3.3 feet) (st. dev.); the Ottawa N.F. trees averaged 2.99 m (9.8 feet)  $\pm$  0.96 m (3.1 feet) (st. dev.). Statistically, the difference is highly significant ( $t=5.705$ ). The degree of superiority is almost identical to the 17.5 percent difference found by Stellrecht, Mohn, and Cromell (1974). As in their study, this superiority in height growth will translate into large differences in volume per tree.

## DISCUSSION

To many tree breeders tree improvement is synonymous with seed orchard establishment either as grafted orchards of phenotypically selected trees or as progeny-test seedling seed orchards. Both are costly and both involve compromises between the amount of genetic gain and efficient seed production. In the grafted orchard, the effectiveness of phenotypic selection will determine the amount of gain. It is most effective on uniform sites in species that occur in pure, even-aged stands. For many species, phenotypic selection in natural stands is not very effective. In addition, roguing genetically inferior clones will reduce seed productivity in grafted orchards.

For maximum improvement, the progeny-test seedling seed orchard will require heavy roguing with resulting inefficient utilization of the site for seed production.

In intensive multigeneration breeding programs of economically valuable species, the key is to keep separate breeding populations and production populations (Kang 1980). Modified seed orchard designs

are also available but they are costly, and they are probably not justifiable with low priority species.

Plantings such as the one we have described may be developed into an effective improvement alternative at low cost. For high priority species, such as the white spruce in our example, such plantings can be an interim source of improved seed. With several such plantings providing parent material, more intensive breeding could be started at some point in the future.

The plantation in our example can be converted to a seed-production area by removing all the trees of the Ottawa N.F. seed source first and then thinning the remaining Beachburg, Ontario trees selectively, leaving approximately 1/4 of the trees. Doing the initial thinning in two separate steps will increase the cost somewhat, but it will facilitate the selective thinning of the trees of the superior seed source. The remaining trees would be at an approximate spacing of 14 x 14 feet (4.2 x 4.2 m), a good spacing for seed production in early years. One later selective thinning, removing 2/3 of the remaining trees, would leave about 70 trees per acre (172/ha) at an average spacing of 24.5 x 24.5 feet (7.5 x 7.5 m). In the selective thinning, the first consideration should be vigor, quality, and absence of pests; the second, spacing of the remaining trees.

In order to assure even spacing of selected trees and to minimize the influence of microsite variation of the selection, a grid could be superimposed on the area, and a predetermined number of individuals selected within each cell of the grid—site quality within a grid cell would tend to be more uniform and selection therefore more effective.

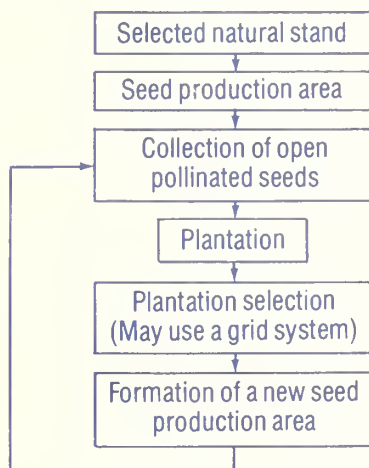

The approach can be used in a multigeneration breeding program. All that will be required is to establish a sequence of plantations always using seed from the previous selectively thinned plantation for each new planting. The approach is low in cost and risk.

Special care should be taken in the nursery in raising the seedlings. Some minor increases in the nursery costs would result. Plantation establishment and maintenance costs would also be higher than usual because special care would be needed in selecting the plantation site and because the best maintenance procedures should be used during establishment. Uniformity of site and maintenance would assure more effective selection. To the degree possible, a site should be selected where the source of outside pollen would be at a minimum to reduce contamination with pollen of low genetical quality.

Negative inbreeding effects with advancing generations could negate the gains achieved early in the program. Large seed collections representing many (100-150) original parent trees would essentially circumvent the problem. If such an original collection were established in a few somewhat different environments and advanced independently from generation to generation, the risk of undesirable inbreeding effects would be further reduced. This is because much of the original genetic diversity could be re-established by mixing the population at some later generation.

Other risks would be small. There will be no major financial loss if the program is abandoned before the selective thinning starts, or at some other stage in its development. The plantings would simply revert to standard uses.

The planting we have described was established with a known superior, broadly adapted source of seed. This is of course an advantage, but it is not essential. Another approach would be to select a high-quality natural stand, develop it into a SPA, and then use the SPA seed for the establishment of the first plantation. This strategy diagrams as follows:

With a network of such plantations over a region, conversion to more intensive breeding programs is possible at any stage. It should be stressed that such a program—and the low-cost program we have described—is environmentally limited to sites similar to sites on which the SPA is established. Future SPA seed established on divergent sites will risk failure. The more the sites diverge from the SPA site, the greater the risk. This, of course, makes the selection of the SPA site particularly important; it must be uniform and representative of the potential planting sites.

The Ottawa trees in the white spruce planting we have described are equivalent to a control. The control permits comparison with currently used planting stock.<sup>2</sup> It is not essential for the breeding, but including such a standard indicates the progress being made.

# DETERMINING LIGHT TRANSMITTANCE CHARACTERISTICS OF WOOD AND BARK CHIPS

Douglas B. Brumm, Associate Professor,  
Electrical Engineering Department,  
Michigan Technological University,  
Houghton, Michigan,

Robert C. Radcliffe, Mechanical Engineering Technician,  
and John A. Sturos, Research Mechanical Engineer,  
Houghton, Michigan

**ABSTRACT.**—Describes computer-assisted testing for measuring light transmittance of wood and bark chips. Electronic interface permitted the computer to collect physical data accurately and efficiently and to analyze and present the data in several tabular and graphical formats.

**KEY WORDS:** Photosorting, mini computers, computer interfacing, computer graphics, bark-chip segregation.

The bark content of wood chips in the pulping process is a critical factor in determining paper quality. With the advent of whole-tree chippers, the percentage of bark has increased, thus degrading the end product. Reducing the bark content would greatly enhance paper quality.

There are various systems for segregating whole-tree chips; one method being investigated is based on the light transmittance characteristics of wood and bark. Light transmittance is the relative amount of light that penetrates the wood or bark chip, usually measured as a percentage of the incident light.

## EXPERIMENTAL APPARATUS

Obtaining statistically valid data on the average light transmittance of bark and wood chips requires the measurement of a large quantity of individual

chips. To facilitate accurate and efficient measurements of light transmittance, we developed an experimental setup that used a mini-computer (fig. 1). In addition to the usual data analysis and storage functions, the computer program also performed a self-calibration of the test fixture (lamp, optical detector, and amplifier) at the beginning of each data set and prompted the operator to insert each new chip at the proper time.

The experimental setup comprised an incandescent light source (a quartz-halogen projector lamp), a photometer, an interface amplifier, an analog-to-digital (A/D) converter, and the computer. The lamp, operated from a regulated DC power supply, furnished a constant light level with no 60 hertz ripple. The photometer was a United Detector Technology<sup>1</sup> model 40X. It will respond either linearly or logarithmically to produce a corresponding electrical output of 0 to 50 millivolts. A fixed aperture was placed over the detector to make the sampled area independent of chip size. The logarithmic mode was used here to permit measurements over a wide dynamic range without changing scales. The interface

<sup>1</sup>The use of trade, firm, or corporation names in this publication is for the information and convenience of the reader. It does not constitute an official endorsement or approval of any product or service by the United States Department of Agriculture to the exclusion of others which may be suitable.

Figure 1.—Setup for measuring light transmittance.

amplifier converts the signal produced by the photometer to that required by the A/D converter. The A/D converter in turn feeds the digital signal into a Hewlett Packard 9825A desk-top computer for data manipulation.

The interface amplifier and the 8-bit A/D converter were designed and assembled by using standard electronic components. The A/D converter has 16 input channels permitting the simultaneous acquisition of a wide variety of electrical signals, although for this application only one channel was used. The photometer output voltage range of interest was 20 to 50 mV. The interface amplifier converts this range to the 0 to 5.2 V input range of the A/D converter as shown in the transfer characteristic (fig. 2). Thus, the input signal was amplified by a factor of 200, then shifted down by about 4.15 V to permit increased A/D resolution in the range of interest. Because the input to the A/D converter must not go below -0.3 V or above +5.4 V under any conditions, the amplifier circuit was also designed to limit at zero and +5.2 V, respectively.

## PROCEDURE

Samples of 5/8-inch wood and bark chips of six Lake States species were tested. Included were quaking aspen (*Populus tremuloides*), balsam fir (*Abies balsamea*), jack pine (*Pinus banksiana*), white spruce (*Picea glauca*), sugar maple (*Acer saccharum*), and red pine (*Pinus resinosa*). All species were tested under both green and oven-dry conditions. A randomly selected group of 50 bark and 50 wood chips of the desired species was sequentially numbered. All successive measurements were then done in sequence to permit correlation of the various data for

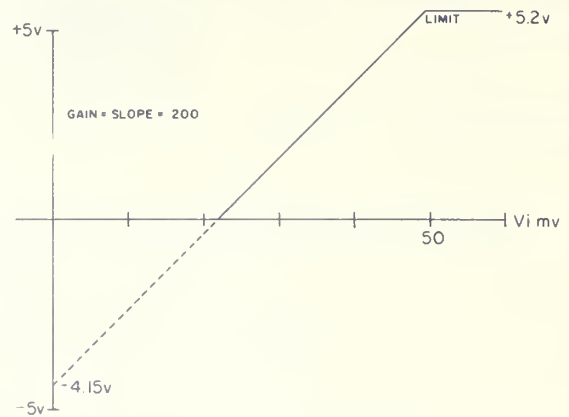

Figure 2.—Transfer characteristic of photometer interface amplifier.

1. Measure wood or bark chip thickness (to 0.001-inch) and key into computer.
2. Place chip in test fixture and initiate automatic light transmittance measurement (by tapping a switch).
3. Manipulate data and store record (done automatically by computer).
4. Dry chips in oven.
5. Remeasure chip thickness and key into computer.
6. Remeasure light transmittance of dry chip.
7. Manipulate dry data and store record (done automatically).

Once the data are in computer memory, they can be presented in graphs (fig. 3) or tables (table 1).

## RESULTS AND CONCLUSIONS

The probability density and distribution functions of the light transmittance (optical density)<sup>2</sup> for two species of green chips is shown in figure 3. The graphs demonstrate the possibility of distinguishing wood from bark in some species by using light transmittance techniques. Aspen demonstrated these qualities best; the other five species showed the same qualities but to a lesser degree (table 1). Jack pine had the least separation of the species measured as also shown in figure 3.

<sup>2</sup>Optical density (O.D.) is defined as the common logarithm of the inverse of light transmittance (T). (O.D. =  $\log_{10} \frac{1}{T}$ ).

Figure 3.—Computer graphs of light transmittance of aspen and jack pine.

For those species with nearly disjoint transmittance distributions, electronic differentiation of a low or high light level passing through each chip can be used to actuate a mechanism to segregate bark and wood (Sturos and Brumm 1978), with the optimum sorting threshold being selected for each species.

Using the computer in this project helped us create an accurate data base. Because of the large quantity of chips required, manually keying the data into the computer would probably have introduced some errors and would have required a more highly trained operator than we used. It also would have required

more time to collect the desired data. The present system can readily be modified for making other automatic measurements by simply altering the amplifier circuit.

# SHEARING RESTORES FULL PRODUCTIVITY TO SPARSE ASPEN STANDS

Donald A. Perala, *Principal Silviculturist,*  
*Grand Rapids, Minnesota*

**ABSTRACT.**—Four mature but grossly understocked (15 to 23 percent of normal) aspen stands were regenerated by suckering following shearing. Eight years later, aspen standing crop varied with site quality from 3.4 to 8.0 tons per acre—nearly the potential for these sites at this age. Shearing is as effective as complete clearcutting for regenerating aspen.

**KEY WORDS:** *Populus tremuloides*, *Populus grandidentata*, root suckers, regeneration, site preparation.

Mature but sparsely stocked quaking and bigtooth aspen (*Populus tremuloides* Michx., *P. grandidentata* Michx.) stands are difficult to regenerate. Most are economically inoperable because of their low volumes, others because of their remoteness or inaccessibility. Even mechanized timber harvesting, the best known way to regenerate aspen, may not be feasible under some circumstances (Perala 1977). So some other means of eliminating the parent stand

and reducing competing trees or tall shrubs is needed to stimulate the initiation and development of root sprouts (suckers) to form a new fully stocked stand (Perala 1977, Schier 1981).

Chainsaw felling, prescribed burning, and poisoning are all useful regeneration tools and each has its advantages and disadvantages. Another possibility is shearing—cutting, and felling trees with a sharp blade mounted on a crawler tractor. Shearing should not be confused with “bulldozing” where trees are merely broken down or uprooted with little or no stimulation of suckering (Forbes and Harvey 1952, Gysel 1957).

Although shearing has been practiced in aspen stands for some time, the minimum stocking required of the parent stand, the soils on which the practice is applicable, and the subsequent development of the sucker stand for timber production have not been documented. To obtain more information on the potential of shearing to regenerate aspen stands, we began a study in 1973 in Sawyer County, Wisconsin. This note summarizes 8 years of aspen development following shearing of understocked aspen stands on soils differing mainly in their drainage characteristics.

## METHODS

In April 1973, about a month before the initiation of shoot growth, four aspen stands in Sawyer County, Wisconsin, were sheared using a sharpened Rome<sup>1</sup> K G blade mounted on a D6 Caterpillar tractor. Although the winter snowpack had melted and the ground was not frozen, soil and root disturbance was minimal. Trees were severed and felled in place without windrowing. Much of the shrub layer was crushed by the equipment, but there was no deliberate attempt to uproot or otherwise destroy it.

Because of the small areas treated, time studies were not kept. Current operational shearing rates are about 2 acres per hour.

The stands were all about 50 years old and ranged in site quality from good to poor (Table 1). The soils were silt loams, varying primarily in soil moisture characteristics (Table 2). Moisture is a prime determinant in the productivity of aspen (Perala 1977).

Within each stand, a 2-acre square study area was established and inventoried from four 0.1 acre circular sample plots prior to shearing. In November 1973, after the first year's production of suckers, 25 1-milacre circular plots were used to systematically sample each stand. Numbers and dominant heights of all woody stems were recorded by species. After 8 years' growth, each stand was again inventoried using the method of nonoverlapping triangles (Loetsch *et al.* 1973) on a 4 x 5 (= 20) sample point grid. Dominant and codominant aspens measured for total height and d.b.h. defined the corners of the triangles. Intermediate and suppressed aspens and other hardwoods were counted within each triangle. The data were summarized and expanded to an area basis according to Loetsch *et al.* (1973). An index of biomass, BH (basal area x mean height), was computed for the dominant trees. Total aspen BH was estimated from a cumulative BH over cumulative stem number function.<sup>2</sup> Total aspen biomass was estimated from Perala (1973).

## RESULTS AND DISCUSSION

The first- and especially the eighth-year inventories showed dramatic responses to shearing and to

| 3     | FREER       | 1-3                  | moderately slow   | 7 to 32                   |
| 4     | FREER       | 1-3                  | moderately slow   | 7 to 32                   |

site quality (Table 3). The number of suckers regenerated and surviving was inversely related to site quality. Indeed, the number of suckers regenerated on the best site was sufficient to give only 68 percent initial stocking. However, by age 8 all stands were fully stocked with 650 to 810 potential crop trees (dominants and codominants) per acre.

Height growth and biomass production were directly related to site quality (Table 3). The sucker stand on the Antigo soil was particularly productive and compared favorably with some highly productive stands of the same age reported elsewhere in the U.S. and Canada (Bella and DeFranceschi 1980; Perala 1973, 1979). Even the least productive stands (Freer soil) were growing at full site potential, judging from comparison with aspen biomass yield tables published by Bella and DeFranceschi (1980).

Hardwood stocking was also directly related to the productivity of these soils (Table 3). Hazel (*Corylus cornuta* Marsh.) and willow (*Salix* spp.) were common in all regenerated stands as was alder (*Alnus rugosa* (Du Roi) Spreng.) on the Antigo soil. The shrubs and hardwoods were developing as an understory beneath the aspens.

<sup>1</sup>Milacre basis.

<sup>2</sup>Northern red oak (*Quercus rubra* L.), paper birch (*Betula papyrifera* Marsh.), red maple (*Acer rubrum* L.).

<sup>3</sup>Dominants and codominants.

<sup>4</sup>Intermediates and suppressed.

This study did not define the lower limit of parent aspen stocking needed for successful regeneration of aspen stands, but it is in the neighborhood of 55 aspens or 18 ft<sup>2</sup> of basal area per acre. Another study (Perala 1981) showed that stocking density of quaking aspen suckers is not diminished up to 17 ft away from mature parent trees. This means that about 50 aspens per acre are needed to provide fully productive stands. That study also showed that sucker stocking was still about 325 stems per acre at 30 ft away. Therefore, about 15 trees per acre will regenerate an irregularly stocked stand that may be acceptably productive, and most likely fully productive after another regeneration cut. For bigtooth aspen, higher parent stand stocking is needed (Perala 1981). Obviously, regular spacing of parent trees is just as important as density to assure full, uniform sucker stocking.

## CONCLUSIONS

Shearing is highly effective in restoring full productivity to severely understocked aspen stands. Based on the relatively high productivity of these sucker stands, there is no reason to believe that shearing is any less effective than complete clearcutting for regenerating aspen. The success of shearing can be attributed mostly to the same reasons that make clearcutting so effective—*i.e.*, the elimination of the aspen overstory which encourages suckering by relieving the apical dominance effect and by allowing warming of the soil with the reduction in shade (Perala 1977, Schier 1981). Reduction of competition by shrubs may have secondary importance.

This study showed that frozen ground is not essential for shearing, if care is taken to avoid excessive scarification and disturbance to aspen roots.

However, research is needed to determine if resistance to uprooting and soil compaction differs significantly among soil textures and moisture regimes.

This study was not designed to determine if shearing effectiveness varies between dormant and growing season. Laboratory and greenhouse studies (Schier 1981) suggest that the period of most active shoot growth (when aspen root carbohydrate levels and, therefore, sucker growth potential are lowest) may be the most sensitive. Field studies by Stoeckeler (1947) and Zehngraff (1946) found reduced sucker numbers and height growth following summer cutting of aspen. Thus, shearing anytime during the dormant period from leaf coloration to bud burst would seem to be most prudent.

# ADJUSTING THE STEMS REGIONAL FOREST GROWTH MODEL TO IMPROVE LOCAL PREDICTIONS

W. Brad Smith, *Mensurationist*

**ABSTRACT.**—A simple procedure using double sampling is described for adjusting growth in the STEMS regional forest growth model to compensate for subregional variations. Predictive accuracy of the STEMS model (a distance-independent, individual tree growth model for Lake States forests) was improved by using this procedure.

**KEY WORDS:** Growth model, double sampling, ratio estimators.

In recent years much effort has been expended to create mathematical models capable of accurately predicting the dynamic processes of forest growth (Fries 1974). Several of these models have been fitted to data from wide geographic areas and broad ranges of site and stand conditions (Arney 1974, Ek and Monserud 1974, Stage 1973, USDA Forest Service 1979).

Frequently, it is desirable to "extend" a model slightly beyond the geographic area for which it was calibrated or to use it intensively within a small portion of the stated range. However, the model may perform poorly for these applications.

When a regional growth model is calibrated using permanent growth plot remeasurement data, the resulting coefficients generally reflect the average of the natural forces operating in that geographic area during the period between remeasurements. Thus, predictions may deviate when the growth model is applied intensively to a subregion within or slightly beyond the geographic range of the model, hence making the regional coefficients inappropriate.

To compensate for such variations, it is seldom practical to recalibrate the entire model. Indeed, all that may be needed is to "fine tune" or "self-calibrate" the existing regional model to improve performance in the subregion or extended area (Stage 1973). This paper describes a simple way to adjust the STEMS regional growth model to compensate for subregional variation.

STEMS is a distance-independent, individual tree growth model currently calibrated for two major geographic areas: the Pacific Northwest and the Lake States (Belcher *et al.* 1981, Shifley 1981, USDA Forest Service 1979, Ek *et al.* 1980, Hahn *et al.* 1979, Smith and Raile 1979, Lundgren and Essex 1979). The Lake States model was calibrated with remeasurement data from approximately 1,500 permanent plots containing 93,000 trees in Minnesota, Wisconsin, and Michigan (Christensen *et al.* 1979). Subsequent validation tests revealed that as one progresses south and east in the Lake States, the predictive power of the Lake States STEMS model diminishes (Leary *et al.* 1979). At the time the model was developed, calibration data were not available from the Upper Peninsula of Michigan and only conifer plantation data were available from the Lower Peninsula. Thus, in effect, applications in Michigan are "extensions" of the current STEMS model.

During the course of a recent field survey in the Upper Peninsula of Michigan, 415 permanent inventory plots that had been previously measured in 1965 were remeasured in 1979. The 8,000 trees on these plots provided the data to calculate growth adjustment factors to improve the predictions of STEMS in this subregion.

# METHODS TO ESTIMATE ADJUSTMENTS

Measurements made in 1965 on the 415 permanent plots formed the basis for a 14-year projection by the STEMS model. The projected tree data were then compared with the data from the 1979 remeasurement to produce a file of initial and final observed d.b.h. and final predicted d.b.h. The file of predicted and observed values was then divided into diameter classes by species group. A correction factor was derived for each species group and diameter class where the data indicated measurable deviation from the growth of the model. This method is an application of double sampling with ratio of means estimators (Cochran 1977).

The diameter increment adjustment, applied to the annual predicted diameter increment, was derived from the following function:

$$GR_{ij} = \frac{\bar{y}_{ij}}{\bar{x}_{ij}}$$

where: GR = annual adjustment factor for diameter increment,  
 i = *i*th species group,  
 j = *j*th d.b.h. class,  
 $\bar{y}$  = mean difference of initial and final observed diameters, and  
 $\bar{x}$  = mean difference of initial observed and final predicted diameters.

Following the derivation of the adjustment factors for growth, a totally independent data set of 9,000 trees from 419 permanent remeasurement plots in the Upper Peninsula of Michigan was used to test the "tuned" STEMS model. The plots were initially measured in 1964 and 1965 and remeasured in 1975.

Validation tests of the adjusted and unadjusted STEMS model were made by comparing prediction errors of the two models for stand basal area and numbers of trees by forest type, and diameter increment by species. Mean annual prediction error and standard deviation were used as measures of bias and precision of the estimates, respectively.

## RESULTS AND DISCUSSION

The annual adjustment rates for diameter increment reflect the magnitude of the subregional deviation from the regionally calibrated model by species group and diameter class (table 1). For all forest types, annual basal area prediction error after ad-

justments decreased nearly five-fold, from an overprediction of 0.60 square feet per acre per year to an overprediction of 0.13 square feet per acre per year (table 2). All forest types except northern white-cedar, oak, and lowland hardwoods improved in precision or bias, and 8 of the 14 types simultaneously reduced bias and increased precision.

Overall, d.b.h. prediction error for the adjusted STEMS model improved 94 percent, from an annual error of 0.033 inches to (-)0.002 inches (table 3). Adjustments by species produced a simultaneous decrease in bias and increase in precision for 16 of the 23 species included in the validation data. Thus, the adjustments to the model reduced bias and increased precision of basal area and d.b.h. predictions, while only modestly changing predictions for number of trees. An overall change in bias was expected, because the adjustments were essentially linear. However, we assumed that the changes in precision were primarily the effect of modified species interactions resulting from the adjustments or the separate ratios by d.b.h. class.

Table 1.—STEMS annual growth increment adjustment factors for the Upper Midwest Peninsula of Michigan.

| Species group   | Trees         | Annual diameter increment adjustment factor |          |                        |
|-----------------|---------------|---|----------|------------------------|
|                 |               | DBH class                                   |          |                        |
|                 |               | 1.0-4.9                                     | 5.0-14.9 | 15.0-24.9 <sup>1</sup> |
|                 | <i>Number</i> |   |          |                        |

were available to calculate factors in the method presented, 32 percent (37 of 132) of the correction factor cells had insufficient data to determine an adjustment (cells containing an adjustment factor of 1.0000 in table 1). This does not include the d.b.h. classes for trees more than 25 inches in diameter that had no cells with sufficient data to calculate a correction factor. An alternative solution would be to derive a single adjustment factor for each species rather than for each species and diameter class. This would reduce the amount of calibration data needed.

It is important to realize that information not available during the original calibration may be added during the adjustment process. Valuable time need not be spent recalibrating the entire model. The calibration data, however, should be representative of the size and vigor of the species to which the adjustment will be applied.

The predictive ability of the STEMS growth model in the Upper Peninsula of Michigan was significantly improved using simple correction factors derived from a recent set of remeasurement data. These adjustment factors transformed the STEMS regional growth model into a more powerful local growth model.

Residual analysis regressing periodic d.b.h. prediction errors of the adjusted and unadjusted STEMS models with initial basal area ( $X_1$ ), initial average stand diameter ( $X_2$ ), initial site index ( $X_3$ ), initial tree crown ratio ( $X_4$ ), and initial tree d.b.h. ( $X_5$ ) was performed using the following test model:

$$\text{residuals} = B_0 + B_1 X_1 + B_2 X_2 + B_3 + B_4 X_4 + B_5 X_5 + e. \quad (1)$$

Most of the variables and their cross products were significant for both the adjusted and unadjusted STEMS models, but the variability explained in each case was minimal (0.04 vs. 0.08 percent according to  $R^2$  values for the adjusted and unadjusted models, respectively). This seems to indicate that a variable or relation not currently considered in the STEMS model may play a significant role in describing the growth process.

Further residual analysis at the tree level indicated that for 10-year periodic diameter increments of 1.5 inches or less, the adjusted model was 81 percent more accurate in explaining prediction error variability ( $R^2$  values of 0.31 and 0.56 for the unadjusted and adjusted models, respectively) and also had a smaller prediction error.

Although STEMS was designed as an individual-tree projection system, predictions of plot characteristics such as basal area and number of trees are also

important. Predicted changes in number of trees were 22 percent more accurate with the adjusted model than the unadjusted model ( $R^2$  values of 0.46 vs 0.56 for the unadjusted and adjusted models respectively). And predicted basal area was 4 percent more accurate with the adjusted model ( $R^2$  values of 0.57 and 0.59, respectively).

Overall, the analysis indicates that the adjusted STEMS model is a better prediction tool for Michigan.

## CONCLUSION

The value of the adjustment process lies in adjusting species when evidence is sufficient to do so. Species for which subregional data are insufficient to determine measurable deviation or for which no significant deviation exists would rely on the regional model calibration to fill in the gaps, thus providing the user with a more powerful "local" model. This process should be of particular interest to STEMS users who own or manage large forest holdings in concentrated areas and have some basic remeasurement information available.

The success of model adjustment ultimately hinges on availability of sufficient quantities of recent remeasurement data for calibrating and validating the selected procedure. Note that even though 8,000 trees

# FOREST AREA IN KANSAS, 1981

Ronald L. Hackett  
 Associate Mensurationist

**ABSTRACT.**—The 1981 forest inventory of Kansas showed that 2.6 percent of the total land area is forested. Commercial forest land accounted for 89 percent or 1,207,900 acres of the forest land and oak-hickory is the major forest type. An important Kansas resource are the 150,000 acres of natural wooded strips.

**KEY WORDS:** Commercial forest land, noncommercial forest land, wooded strips, land use, forest type.

The forest land of Kansas occupies 1.4 million acres, about 2.6 percent of the total land area (table 1). Forest land can be broken down into two elements: commercial and noncommercial forest land. Commercial forest land—that suitable for producing industrial timber—accounts for 1,207,900 acres (89 percent) of the forest land in Kansas. This is an increase of 16,400 acres (1.4 percent) since the last inventory.

than timber production such as parks and natural areas. The remaining 128,400 acres are unproductive forest land too poor to grow timber for industrial use.

Most of the commercial forest land occurs in the eastern part of the State along the Missouri River and several other rivers (fig. 1). Linn County, located in the Southeastern Unit of the State, contains 48,700 acres of commercial forest land—more than any other county in the State (table 1). And Leavenworth County in the Northeastern Unit has the largest percentage of commercial forest with 14.6 percent.

Oak-hickory makes up 26.2 percent of the commercial forest area and is the largest forest type, elm-ash-cottonwood accounts for 24.0 percent of the commercial forest area and is the second largest forest type, willow makes up 0.3 percent of the commercial forest area and is the smallest forest type:

Noncommercial forest land in Kansas amounted to 150,800 acres in 1981. Of this amount, 22,400 acres were productive but reserved for uses other

<sup>4</sup>Elm-ash-cottonwood type is a lowland forest in which elm, ash, cottonwood, and willow, singly or in combination, comprise a plurality of the stocking.

<sup>5</sup>Cottonwood type is forest in which cottonwood comprises a majority of the stocking.

<sup>1</sup>1965 data have been adjusted to be compatible with 1981 data due to changes in definitions between surveys.

<sup>2</sup>From U.S. Bureau of Census. 1960.

<sup>3</sup>From U.S. Bureau of Census. 1980.

<sup>1</sup>U. S. Bureau of Census, 1980.<sup>2</sup>Land at least 16.7 percent stocked by forest trees of any size or land formerly having such tree cover, excludes land currently developed for nonforest use such as urban or heavily settled residential or resort area, city parks, orchards, improved roads, or improved pasture. The minimum forest area classified was 1 acre. Roadside, streamside, and shelterbelt strips of timber with a crown at least 120 feet wide and unimproved roads and trails, streams, and clearings in forested areas if less than 120 feet wide were classified as forest.<sup>3</sup>Unproductive forest land incapable of yielding crops of industrial wood because of adverse site conditions, and productive public forest land withdrawn from commercial timber production through statute or administrative regulation.<sup>4</sup>Forest land producing or capable of producing crops of industrial wood and not withdrawn from timber utilization by statute or administrative regulation.<sup>5</sup>Area of land with trees but less than 16.7 percent stocked, and/or area less than 120 feet wide, i. e., cropland with scattered trees, improved pasture with scattered trees, wooded strips, windbreaks, and idle farmland with scattered trees.<sup>6</sup>An acre or more of continuous forest land that would otherwise meet the standards for commercial forest land except that it is less than 120 feet wide.

SOUTHEASTERN UNIT

PERCENT FORESTED

Figure 1.—Percent of commercial forest land by county, Kansas, 1981.

An important Kansas resource not included in the forest land area is the nonforest with trees category, and particularly the 150,000 acres of natural wooded strips. These areas meet all the requirements for commercial forest land except they are less than 120 feet wide:

**Nonforest with trees land class**

Improved pasture or rangeland with scattered trees<sup>6</sup>  
 Wooded pasture<sup>7</sup>  
 Windbreaks<sup>8</sup>  
 Natural wooded strips  
 Cropland with scattered trees  
 Idle farmland with scattered trees  
 Marshland with scattered trees

**Area of nonforest with trees**  
(Thousand acres)

533.6  
 209.8  
 186.3  
 150.0  
 63.0  
 23.9  
 22.7

Total 1,189.3

The information in this note comes from the third Kansas forest inventory made during 1980 and 1981 by the North Central Forest Experiment Station and the Kansas State and Extension Forester's office.

Sampling error for this survey was 2.45 percent for the area of commercial forest land.

<sup>6</sup>Improved pasture or rangeland with trees—land currently improved for grazing by cultivating, seeding, irrigating, or clearing of trees or brush, that is less than 16.7 percent stocked with all trees.

<sup>7</sup>Wooded pasture—pasture land with more than 16.7 percent stocking in all trees, but less than 25 percent stocking in growing-stock trees, and would qualify as pastured commercial forest land except that the primary land use is grazing. Evidence of grazing is severely compacted soil and heavily browsed herbaceous and woody understory.

<sup>8</sup>Windbreaks—a group of trees less than 120 feet wide primarily used for protecting buildings, soil, and cropland.

# ALLOMETRIC BIOMASS EQUATIONS FOR 98 SPECIES OF HERBS, SHRUBS, AND SMALL TREES

W. Brad Smith, *Mensurationist*,  
 and Gary J. Brand, *Associate Mensurationist*

**ABSTRACT.**—Biomass regression coefficients from the literature for the allometric equation form are presented for 98 species of shrubs and herbs in the northern U.S. and Canada. The equation and coefficients provide estimates of grams of biomass (oven-dry weight) for foliage, woody stem and total biomass.

**KEY WORDS:** Regression, metric, dry weight, herbs, shrubs.

Biomass estimates for herbs and shrubs have many uses in determining wildlife habitat and forest fuel conditions. Although many independent variables and equations have been chosen in biomass studies, the simple allometric equation is most frequently used (Stanek and State 1978, Hitchcock and McDonnell 1979). This equation for predicting biomass in grams (Y) from stem diameter or percent cover (X) has two forms:

$$Y = aX^b \quad (1)$$

or

$$\ln Y = a + b \ln X, \quad (2).$$

The purpose of this paper is to compile coefficients for these equations for species in eastern Canada and the northern United States from seven sources (Telfer 1969, Grigal and Ohmann 1977, Ohmann *et al.* 1976, Brown 1976, Roussopoulos and Loomis 1979, Ohmann *et al.* 1981, Connolly 1981).

For convenience, Eq. 2 may be put in the form of Eq. 1 by solving for Y and transforming the coefficients. The new equation becomes:

$$Y = a' X^b \quad (3)$$

where  $a' = e^a$  and coefficients a and b are the same as in Eq. 2. The equation coefficients from Ohmann *et al.* (1976), Grigal and Ohmann (1977), Roussopoulos and Loomis (1979), Ohmann *et al.* (1981), and Connolly (1981) are taken directly from the original sources. Telfer (1969) and Brown (1976) reported coefficients for the logarithmic form, which we converted. Telfer's coefficients were additionally adjusted to convert the independent variable from basal diameter in mm to cm. Thus, for Telfer  $a' = e^a 10^b$  in Eq. 3.

Roussopoulos and Loomis fit their data to Eq. 2 but converted these coefficients after correcting for the bias inherent in the fitting of the logarithmic form (Baskerville 1972, Yandle and Wiant 1981). Brown indicated that the effects of this bias on his biomass estimates ranged from 2 to 9 percent with an average of 5 percent. The coefficients presented by Brown are unadjusted for bias, as are those presented by Telfer. All coefficients presented are for estimating biomass in grams oven-dry weight.

One caution is necessary: some of the equations use stem diameter at 15 cm as the independent variable and others use basal diameter. Roussopoulos and Loomis (1979) present a regression technique for estimating basal diameter at 15 cm, thereby facilitating the use of basal diameter equations even though field measurements may have been collected at 15 cm.

Refer to the original publications for details about methods, specific locations of data sources, or any other questions regarding the biomass studies.

Table 1.--Coefficients and related statistics for the allometric relationship, Biomass =  $ax^b$ 

| Species                            | Biomass <sup>1</sup> / <sub>key</sub> | Independent <sup>2</sup> / <sub>variable (x)</sub> | Coefficients <sup>2</sup> / <sub>a b</sub> | Number of observations | R <sup>2</sup> | Range of independent variable | Location <sup>3</sup> / <sub>Source</sub> |

<sup>1/</sup> Biomass in grams oven-dry weight; T = total aboveground biomass; W = woody aboveground biomass; and F = foliage biomass.

<sup>2/</sup> D1 = basal diameter in cm and D2 = diameter at 15 cm aboveground in cm.

<sup>3/</sup> Canada = Maritime Provinces, ID = northern Idaho, MN = northern Minnesota, and MT = western Montana.

## DIMENSIONAL CHARACTERISTICS OF HARDWOOD TOP AND LIMB RESIDUE

Nels S. Christopherson, *Research Mechanical Engineer,*  
*Houghton, Michigan*

**ABSTRACT.**—Sawtimber harvesting in northern hardwood stands leaves behind a large amount of residue in the form of tops and limbs. This paper presents typical dimensional characteristics of residue for northern hardwood tops including data on lengths, widths, diameters, and complete branch details.

**KEY WORDS:** Wood energy, delimiting, biomass utilization, harvesting, topwood residue.

The abundant supply of wood in the United States has led to some wasteful practices, especially with respect to sawtimber residue. Developing new technology and markets will help encourage the utilization of these residues and thus reduce the needless waste of a natural resource.

USDA Forest Service scientists have determined that, after northern hardwood sawtimber harvesting, between 40 and 50 percent of a tree's weight above the stump is left as residue (Mattson and Carpenter 1975). For example, the average topwood residue weight from a 21-inch-d.b.h. sugar maple tree is about 2,000 pounds (Steinhilb and Winsauer 1976). If this single top were recovered for energy, it would be equivalent to one 42-gallon barrel of oil. In the Eastern U.S., an estimated 50 million dry tons of hardwood residue in the form of tops and limbs remain each year after harvesting (Carpenter 1980).

What makes topwood residue rather unique is that it becomes "available" for essentially a zero prior investment because current practice in timber harvesting depreciates the whole tree at time of harvest while utilizing only the saw log portion. This practice

will eventually change as topwood harvesting becomes commonplace, but it presently provides an economic incentive.

Continuing research studies are investigating methods to recover this topwood residue. A complete recovery system would include schemes for:

1. Removing the residue from the forest to a landing or roadside,
2. transporting it to a location for further processing, or,
3. processing it in the forest or at the landing and then transporting it.

For the key elements—handling, transportation, and processing—certain facts must be known such as volumes per acre, weights, number of pieces per acre, and physical size of the material. Previous research studies have documented the volumes, weights, and densities per acre of residue tops and limbs (Winsauer and Steinhilb 1980, Steinhilb and Dye 1973, Grantham and Howard 1980, Bradley *et al.* 1980).

What has not been documented are the dimensional characteristics of topwood residue. To design both efficient and economical equipment to handle, transport, or process a top, researchers must know the actual diameters of the main stem and branches. Other details such as the number of branches and their angle with the main stem are also necessary, especially to design equipment to remove limbs. The results presented here will help to fill the gap in engineering data by providing the dimensional characteristics of hardwood top and limb residue. No attempt was made to document the density of tops per a given area or estimate weights or board feet, etc.

## DESCRIPTION OF SITES

The topwood data presented in this paper came from a sample of 64 tops. To attempt to eliminate any bias due to logging practice or site differences, the tops were selected from three separate sites. All three sites were mixed northern hardwood stands on rolling terrain in the Upper Peninsula of Michigan: one in Houghton County, one in Keweenaw County, and one in Baraga County. The sites in Houghton and Keweenaw Counties, located on land owned by the Copper Range Company, were marked by that company for the sawtimber harvesting that took place approximately 6 months before the topwood measuring. The Baraga County site, owned by Michigan Technological University, was also marked and cut about 6 months earlier. All three sites were logged by different loggers. These sites were managed and marked for a selective sawtimber harvest which precludes the harvesting of trees under a certain minimum d.b.h. (usually 12 inches).

The breakdown of species of tops for each site is:

Baraga County—13 red maple (*Acer rubrum*)  
6 sugar maple  
(*Acer saccharum*)  
1 elm (*Ulmus americana*)

Houghton County—23 sugar maple  
(*Acer saccharum*)  
1 yellow birch  
(*Betula alleghaniensis*)

Keweenaw County—19 sugar maple  
(*Acer saccharum*)  
1 yellow birch  
(*Betula alleghaniensis*)

## PROCEDURE

At least 20 tops at each site were measured to provide representative data for a "typical" hardwood top. For each top measured, the following data were recorded with all diameters "outside bark" (d.o.b.):

1. Species.
2. Stump diameter.  
All stumps were identified for each top, and diameters were measured at approximately 1 foot above the ground.
3. Stump to top butt distance (merchantable length).  
Measured 1 foot from stump to butt of top along ground.
4. Butt diameter of top.
5. Length of top.  
Length from top butt to top of foliage.
6. Crown width (maximum).

7. Branch data for those greater than 4 inches d.o.b.  
The number of branches, the location of their juncture with the main stem, their angle with the main stem, and their length to 4 inches d.o.b.
8. Number of branches less than 4 inches d.o.b.

## DATA ANALYSIS

The first step in the analysis was to establish whether any site or species differences existed. The data were grouped into the following variables by site: Species; stump to top butt distance; stump diameter; top butt diameter; crown width; top length; number of branches in each of six branch classes by diameter in inches, 0-3.9, 4-5.9, 6-7.9, 8-9.9, 10-11.9, 12-15; and branch angle with the main stem of 0-29, 30-59, or 60-90 degrees. From an engineering viewpoint, there are no major site differences as evidenced by means and corresponding standard deviations of the variables. By comparing the results of Houghton and Keweenaw Counties (predominately sugar maple) to those of Baraga County (predominately red maple), there again proved to be no major species differences. Based on these results, all further analysis was done using all 64 residue tops treated as one group.

## RESULTS AND CONCLUSIONS

Figure 1 shows a typical northern hardwoods residue top with mean dimensions and their corresponding standard deviations. In addition, the histograms in figures 2 through 6 give a more detailed breakdown of the dimensions.

Topwood is available, but it cannot be just skidded out intact. Because of the average length (36 feet) and width (25 feet) of a top, skidding would seriously damage the residual stand. Reducing the top by manual chain sawing is both costly and unsafe. What looks most promising is a mechanized scheme in which the tops are first reduced and then transported to a landing for further processing.

The details of branch sizes and lengths are shown in table 1 and in figures 7 and 8. Table 1 and figure 7 include only data on the branches themselves, not on the main stems. Figure 8, which presents information on the lengths of roundwood greater than 4 inches d.o.b., includes data on both branches and main stems. The data presented in figure 8 strongly suggest that this material could be utilized for higher value solid wood products rather than simply for chips for fiber and/or fuel.

Figure 2.—Distribution of stump diameters for 64 stumps.

Figure 3.—Distribution of merchantable lengths for 64 trees (stump to top butt distances).

Figure 4.—Distribution of top butt diameters for 64 tops.

Figure 5.—Distribution of maximum crown widths for 64 tops.

Figure 6.—Distribution of crown lengths for 64 tops.

Figure 7.—Distribution of branch size classes for 64 tops. (Does not include main stem.)

Figure 8.—Distribution of lengths of roundwood greater than 4 inches d.o.b. for 64 tops. (Includes both main stem and branches.) NOTE: Total number of pieces is 393; mean length is 7.9 feet (std. dev. = 6.7).

Table 1.—Branch details<sup>1</sup>

| Branch size class (inches) | Number of branches per top |      |
|----------------------------|----------------------------|------|
|                            | Range                      | Mean |
| 0- 3.9                     | 2-34                       | 15.3 |
| 4- 5.9                     | 0-7                        | 3.3  |
| 6- 7.9                     | 0-7                        | 1.9  |
| 8- 9.9                     | 0-2                        | .5   |
| 10-11.9                    | 0-2                        | .2   |
| 12-15                      | 0-2                        | .1   |

<sup>1</sup>Does not include main stem.

For branches greater than 4 inches d.o.b., the angle with the main stem is distributed as follows:

|               |            |
|---------------|------------|
| 0-30 degrees  | 33 percent |
| 30-60 degrees | 44 percent |
| 60-90 degrees | 23 percent |

A correlation matrix was calculated for all variables. There proved to be no relations that would be useful from an engineering viewpoint. The largest correlation is stump diameter versus top butt diameter with an  $r$  value of 0.53. The next largest is branch class six versus top butt diameter with an  $r$  of 0.51. All other correlations were negligible.

Further research is needed on various schemes and devices to harvest northern hardwood top and limb residue. The results presented here have established a representative set of engineering data to guide this research.
